CALCULUS, in *Mathematics;* the lower or common analysis. It contains the rules necessary to calculate quantities of any definite magnitude whatever. But quantities are sometimes considered as varying in magnitude, or as having arrived at a given state of magnitude by successive variations. This gives rise to the higher analysis, which is of the greatest use in the physico-mathematical sciences. Two objects are here proposed: First, to descend from quantities to their elements. The method of effecting this is called the *differential calculus*. Second, to ascend from the elements of quantities to the quantities themselves. This method is called the *integral calculus*. Both of these methods are included under the general name *infinitesimal analysis*. Those quantities which retain the same value are called *constant;* those whose values are varying are called *variable*. When variable quantities are so connected that the value of one of them is determined by the values ascribed to the others, that variable quantity is said to be a *function* of the others. A quantity is *infinitely great* or *infinitely small*, with regard to another, when it is not possible to assign any quantity sufficiently large or sufficiently small to express the ratio of the two. When we consider a variable quantity as increasing by infinitely small degrees, if we wish to know the value of those increments, the most natural mode is to determine the value of this quantity for any one instant, and the value of the same for the instant immediately following. This difference is called the *differential* of the quantity. The *integral calculus*, as has been already stated, is the reverse of the *differential calculus*. There is no variable quantity expressed algebraically, of which we cannot find the differential; but there are differential quantities, which we cannot integrate: some, because they could not have resulted from *differentiation;* others, because means have not yet been discovered of integrating them.

We have made these elementary observations for the purpose of introducing the history of the discovery of this mighty instrument. For a full examination of the subject, we refer to Lacroix's works, Carnot's *Métaphysique du Calcul Infinitesimal*, Lagrange's *Calcul des Fonctions*. Newton was the first discoverer, having pointed out the principles in a treatise written before 1669, but not published till many years after. Leibnitz, meanwhile, made the same discovery, and published it to the world before Newton, and independently of Newton's prior discoveries, with a much better notation, which is now universally adopted. The methods analogous to the infinitesimal analysis previously employed were that of *exhaustions*, known to the ancients, that of *indivisibles* of Cavalieri, and Descartes' method of *indeterminates*. Leibnitz considered the differences of the variable quantities as infinitely small, and conceived that he might reject the higher powers of those differences without sensible error; so that none of those powers but the first remained in the differential equation finally obtained. Instead of the actual increments of the *flowing* or variable quantities, Newton introduced the *fluxions* of those quantities; meaning, by fluxions, quantities which had to one another the same ratio which the increments had in their ultimate or evanescent state. The *fluxions* of Newton corresponded with the *differentials* of Leibnitz; and the *fluents* of the former with the *integrals* of the latter. The fluxionary and the differential calculus are therefore two modifications of one general method.

The problems which relate to the *maxima* and *minima*, or the greatest and least values of variable quantities, are among the most interesting in mathematics. When any function becomes either the greatest or the least, it does so by the velocity of its increase or decrease becoming equal to nothing: in this case, the fluxion which is proportional to that velocity must become nothing. By taking the fluxion of the given function, and supposing it equal to nothing, an equation may be obtained in finite terms, expressing the relation of the quantities when the function assigned is the greatest or least possible. The new analysis is peculiarly adapted to physical researches. The momentary increments represent precisely the forces by which the changes in nature are produced: so that this doctrine seemed created to penetrate into the interior of things, and take cognizance of those powers which elude the ordinary

methods of geometrical investigation. It alone affords the means of measuring forces, when each acts separately and instantaneously, under conditions that can be accurately ascertained. In comparing the effects of continued action, the variety of time and circumstance, and the continuance of effects after their causes have ceased, introduce uncertainty, and render the conclusions vague and unsatisfactory. The analysis of infinites here goes to the point; it measures the intensity or instantaneous effort of the force, and removes all those causes of uncertainty. It is by effects, taken in their nascent or evanescent state, that the true proportion of causes must be ascertained.

Calculus. Little stones, anciently used for computation, voting, &c., were called *calculi*. The Thracians used to mark lucky days by white, and unlucky by black pebbles; and the Roman judges, at an early period, voted for the acquittal of the accused by a white, and for condemnation by a black calculus: hence, *niger* or *albus calculus*, a favourable or unfavourable vote. Sometimes the ballots were marked with characters, and then were made of wood. *Calculi lusorii* or *latrones* were counters used in a game, something like backgammon. *Calculus Minervæ* was an expression employed to signify that the accused escaped by an equal division of the votes of the judges. He was said to be acquitted *calculo Minervæ* (by the vote of Minerva), because Orestes was acquitted by the vote of that goddess when the judges were equally divided.

Calculus, or Stone, is the name given to all hard concretions, not bony, formed in the bodies of animals. Calculi may be divided into two classes, according as they are found in the gall-bladder or in the urinary bladder. The first are called *biliary calculi*, the second *urinary calculi*.

Biliary calculi are of a lamellated structure, and are composed of a substance which is considered by M. Chevreul as a peculiar principle, which he has named *cholesterine*. It is described as a white crystalline substance, with much lustre, insipid and inodorous, much resembling spermaceti, but differing in being less fusible, and in not forming a soap with alkalies. It is also converted, by the action of nitric acid, into a peculiar acid, called *cholesteric acid*. This is slightly soluble in water, and forms soluble salts with the alkalies. Cholesterine consists of carbon 85.095, oxygen 3.025, and hydrogen 11.88. It has lately been detected in the bile itself, both in that of animals and of man. Besides cholesterine, biliary concretions contain a portion of inspissated bile, and the yellow colouring matter of the bile in a concentrated state, which from the beauty and permanence of its hue, is much valued as a pigment.

Urinary calculi are of very variable characters and composition. The following substances enter principally into their composition: uric acid, urate of ammonia, phosphate of lime, phosphate of ammonia and magnesia, oxalate of lime, silex, sometimes oxide of iron and animal matter—these being more or less pure or mixed, and being often diversified by mechanical structure, so as to render it difficult to constitute well-defined species. The six following species embrace the principal varieties of urinary calculi: 1. that composed chiefly of uric acid; 2. that consisting chiefly of the triple phosphate of ammonia and magnesia; 3. the bone-earth calculus, formed almost entirely of phosphate of lime; 4. the fusible calculus, composed of the two preceding intermixed; 5. the mulberry calculus, consisting of oxalate of lime; and, 6. a rare species, the cystic oxide calculus. Two others, still more rare, are the xanthic oxide and fibrinous calculus, discovered by Doctor Marcet; and, lastly, calculi have been met with formed of carbonate of lime. In all these calculi, besides the saline matter, there is present a portion of animal matter, which is conceived to be the mucus of the bladder. This seems to give them colour and induration. It is found even in those which are white and crystalline. In the mulberry calculus it is present in a larger proportion than in the others. The ingredients of calculi are often, also, diversified by intermixture in layers. These must, of course, be various, and as their production is in some measure accidental, irregularly arranged. Those which have been the most frequently observed are alternations of uric acid with phosphate of magnesia and ammonia, or phosphate of lime; or of oxalate of lime with uric acid, or with either or both of these phosphates.

Calendar; the division of time into years, months, weeks, and days; also a register of these divisions. Among the old Romans, for want of such a register, it was the custom for the *pontifex maximus*, on the first day of the month, to proclaim (*calare*) the month with the festivals occurring in it, and the time of new moon. Hence *calendæ* and *calendar*. The periodical occurrence of certain natural phenomena gave rise to the first division of time. The apparent daily revolution of the starry heavens and the sun about the earth occasioned the division into days. But, as the number of days became too great for convenience, some larger measure of time was found necessary. The changes of the moon, which were observed to recur every 29 or 30 days, suggested the division of time into months. After a considerable period these also were found to multiply too much, and a still larger measure of time was wanted. Such a one was found in the apparent yearly revolution of the sun round the earth in the ecliptic. The time of this revolution, after several erroneous calculations hereafter to be mentioned, was finally determined to be a little more than 365 days. This was called a *solar year*, or simply a *year*, which was divided according to the former measures of time, into months and days. Now, on account of the great influence of the sun's course in the ecliptic, and its consequent variations of distance from us upon the earth, and the affairs of its inhabitants in all countries, the attention of men would naturally be drawn to this phenomenon. Hence it has happened that all nations, in any degree civilized, have adopted the year as the largest measure of time. It is probable that the Phœnicians first, then the Egyptians, and afterwards the Greeks, made use of this mode of reckoning, from whom it was communicated to other nations. The division of the year, however, into months and days, could not have been very accurate at first, because it can be settled only by long and attentive observation. The calendar of the oldest nations was quite imperfect. They were satisfied with one which enabled them to manage the common business of husbandry.

The Greeks were the first who attempted to adjust the courses of the sun and the moon to each other. For this purpose, they reckoned 12½ revolutions of the moon round the earth for one solar year; and, to avoid the fractions of a month, they made the year consist of 13 and 12 months alternately. Solon,

perceiving the defects of this arrangement, fixed the number of days in a month at 29½, and made the month consist of 29 and 30 days alternately. Still the length of the month and that of the year were not brought into exact adjustment, and new disorders soon followed. Various plans for the reformation of the calendar were proposed from time to time; but all proved insufficient, till Meton and Euctemon finally succeeded in bringing it to a much greater degree of accuracy, by fixing on the period of 19 years, in which time the new moons return upon the same days of the year as before (as 19 solar years are very nearly equal to 235 lunations). This mode of computation, first adopted by the Greeks (433 B. C.), was so much approved of, that it was engraven with golden letters on a tablet at Athens. Hence the number showing what year of the moon's cycle any given year is, is called the *golden number*. This period of 19 years was found, however, to be about six hours too long. This defect, Calippus, about 102 years later, endeavoured to remedy, but still failed to make the beginning of the seasons return on the same fixed day of the year. Among the Romans, their first king, Romulus, introduced a year of 10 divisions or months, of which four (March, May, July, and October) contained 31 days; the rest (April, June, August, September, November, and December), only 30. When he discovered that this mode of reckoning was imperfect, he inserted as many days as were necessary to complete the year, and bring it up to the beginning of the following one. His successor, Numa Pompilius, abolished this method, added 50 days more, took one day from each of the six months containing 30 days, because even numbers were considered unlucky, and out of the whole 26 days formed two new months of 28 days each, which he called *January* and *February*. Thus the year consisted of 12 months, and 350 days; and to make it agree with the course of the sun, intercalations were made use of, after the manner of the Greeks. These intercalations, however, were left to the discretion of the priests; and, as they made them very arbitrarily, according to the exigencies of the state, or their own private views, complaints and irregularities soon arose. Notwithstanding this defect, the arrangement continued to the end of the republican constitution.

The calendar of the Romans had a very peculiar arrangement. They gave particular names to three days of the month. The first day was called the *calends*. In the four months of March, May, July, and October, the 7th, in the others, the 5th day, was called the *nones*; and, in the four former, the 15th, in the rest, the 13th day, was called the *ides*. The other days they distinguished in the following manner: they counted from the above-mentioned days backwards, observing to reckon also the one from which they began. Thus the 3d of March, according to the Roman reckoning, would be the 5th day before the *nones*, which in that month fall upon the 7th. The 8th of January, in which month the *nones* happen on the 5th, and the *ides* on the 13th, was called the 6th before the *ides* of January. Finally, to express any of the days after the *ides*, they reckoned in a similar manner from the calends of the following month. From the inaccuracy of the Roman method of reckoning, it appears that, in Cicero's time, the calendar brought the vernal equinox almost two months later than it ought to be. According to the last letter of the 10th book of *Cicero's Letters to Atticus*, this equinox was not yet past, although it was near the end of May, by their calendar. To check this irregularity, Julius Cæsar, on being appointed dictator and pontiff (A. U. C. 707), invited the Greek astronomer Sosigenes to Rome, who, with the assistance of Marcus Fabius, invented that mode of reckoning, which after him who introduced it into use, has been called the *Julian calendar*. The chief improvement consisted in restoring the equinox to its proper place in March. For this purpose, two months were inserted between November and December, so that the year 707, called, from this circumstance, the *year of confusion*, contained 14 months. In the number of days, the Greek computation was adopted, which made it 365¼.

The number and names of the months were kept unaltered, with the exception of Quintilis, which was henceforth called, in honour of the author of the improvement, *Julius*. To dispose of the quarter of a day, it was determined to intercalate a day every fourth year, between the 23d and 24th of February. This was called an *intercalary* day, and the year in which it took place was called an *intercalary* year, or as we term it, a *leap* year. This calendar continued in use among the Romans until the fall of the empire, and throughout Christendom till 1582. The festivals of the Christian church were determined by it. With regard to Easter, however, it was necessary to have reference to the course of the moon. The Jews celebrated Easter (the Passover) on the 14th of the month Nisan (or March); the Christians in the same month, but always on a Sunday. Now, as the Easter of the Christians sometimes coincided with the Passover of the Jews, and it was thought unchristian to celebrate so important a festival at the same time as the Jews did, it was resolved at the Council of Nice, 325 A.D., that from that time Easter should be solemnized on the Sunday following the first full-moon after the vernal equinox, which was then supposed to take place on the 21st of March. As the course of the moon was thus made the foundation for determining the time of Easter, the lunar cycle of Meton was taken for this purpose; according to which the year contains 365¼ days, and the new moons, after a period of 19 years, return on the same days as before. The inaccuracy of the Julian year, thus combined with the lunar cycle, must have soon discovered itself, on a comparison with the true time of the commencement of the equinoxes, since the received length of 365¼ days exceeds the true by about 11 minutes; so that for every such Julian year, the equinox receded 11 minutes, or a day in about 130 years. In consequence of this, in the 16th century, the vernal equinox had changed its place in the calendar from the 21st to the 10th; that is, it really took place on the 10th instead of the 21st, on which it was placed in the calendar.

Aloysius Lilius, a physician of Verona, projected a plan for amending the calendar, which, after his death, was presented by his brother to Pope Gregory XIII. To carry it into execution, the pope assembled a number of prelates and learned men. In 1577, the proposed change was adopted by all the Catholic princes; and in 1582, Gregory issued a brief abolishing the Julian calendar in all Catholic countries, and introducing in its stead the one now in use, under the name of the *Gregorian* or *reformed calendar*, or the *new style*, as the other was now called the *old style*. The amendment consisted in this:—10 days

were dropped after the 4th of October, 1582, and the 15th was reckoned immediately after the 4th. Every 100th year, which, by the old style was to have been a leap year, was now to be a common year, the 4th excepted; i.e., 1600 was to remain a leap year, but 1700, 1800, 1900, to be of the common length, and 2000 a leap year again. In this calendar the length of the solar year was taken to be 365 days, 5 hours, 49 minutes, and 12 seconds. Later observations of Zach, Lalande, and Delambre, fix the average length of the tropical year at about 27 seconds less; but it is unnecessary to direct the attention of the reader to the error arising from this difference, as it will amount to a day only in the space of 3000 years.

Notwithstanding the above improvement, the Protestants retained the Julian calendar till 1700, when they also adopted the new style, with this difference, that they assigned the feast of Easter to the day of the first full moon after the *astronomical* equinox. But this arrangement produced new variations. In 1724 and 1744, the Easter of the Catholics was eight days later than that of the Protestants. On this account, the Gregorian calendar was finally adopted, 1777, in Germany, under the name of the *general calendar of the empire*, or as it is now called, the *reformed calendar*, in order that the Catholics and Protestants might celebrate Easter, and, consequently, all the moveable feasts at the same time. England introduced the new style in 1752, and Sweden in 1753. Russia only retains the old style, which now differs 12 days from the new.

In France, during the revolution, a new calendar was introduced, by a decree of the National Convention, Nov. 24, 1793. The time from which the new reckoning was to commence was the autumnal equinox of 1792, which fell upon the 22d of Sept., at 18 minutes and 30 seconds after 9 A. M., Paris time. This day was selected as that on which the first decree of the new republic had been promulgated. The year was made to consist of 12 months of 30 days each, and, to complete the full number of days, 5 *jours complementaires* were added to the end of it, in common years, and 6 in leap years. Each period of 4 years, terminating with a leap year, was called a *franciade*. Instead of weeks, each month was divided into 3 parts, called *decades*, consisting of 10 days each; the other divisions being also accommodated to the decimal system. The names of the months were so chosen as to indicate by their etymology, the time of year to which they belonged. They were as follows:—Autumn, from the 22d Sept. to the 22d Dec.; *Vendémiaire*, vintage month (Oct.); *Brumaire*, foggy month (Nov.); *Frimaire*, sleet month (Dec.):—Winter, from 22d Dec. to 22d March; *Nivôse*, snowy month (Jan.); *Ventôse*, windy month (Feb.) *Pluviôse*, rainy month (March):—Spring from 22d March to 22d June; *Germinal*, bud month (April); *Floréal*, flower month (May); *Prairial*, meadow month (June):—Summer, from 22d June to 22d Sept.; *Messidor*, harvest month (July); *Thermidor*, hot month (Aug.); *Fructidor*, fruit month (Sept.). The 10 days of each decade were called, 1. *Primidi*, 2. *Duodi*, 3. *Tridi*, 4. *Quartidi*, 5. *Quintidi*, 6. *Sextidi*, 7. *Septidi*, 8. *Octidi*, 9. *Nonidi*, 10. *Decadi* (the Sabbath). Besides this, each day in the year had its particular name, appropriate to the time when it occurred; as, the 7th of Vintage month, *Vendémiaire*, was named *carottes* (carrots). This calendar was abolished, at the command of Napoleon, by a decree of the senate, 9th Sept., 1805, and the common Christian or Gregorian calendar introduced throughout the French empire.

CALENDER. Different fabrics, before they leave the hands of the manufacturer, are subjected to certain processes, the object of which is to make them smooth and glossy, to glaze them, to water them, or give them a wavy appearance. This is done, in general, by pressing the fabric between wooden or metallic cylinders, whence the machine is called a *calender*, and the workman a *calender* or *calenderer*.

CALENDS, with the Romans, the first days of the month; so called because the *pontifex maximus* then proclaimed (*calavit*) whether the *nones* would be on the 5th or the 7th. This was the custom until the year 450 U.C., when the *fasti calendares*, or calendar were affixed to the wall of public places. The Greeks did not make use of calends; whence the proverbial expression *ad Græcas calendas* (on the Greek calends), meaning *never*. The calends of January were more solemn than the others, and were consecrated to Janus and Juno. On this day the magistrates entered on their offices, and friends interchanged presents. On the calends, debtors were obliged to pay the interest of their debts; hence *tristes calendæ*. The book of accounts was called *Calendarium*.

CALENTURE; a violent fever, incident to persons in hot climates, especially to such as are natives of cooler climates. It is attended with delirium; and the patient imagines the sea to be a green field, in which he is tempted to walk by the coolness and freshness of its appearance. This is, at least, the poetical explanation of the matter. The fact seems to be, that the intense inflammation of the fever prompts the patient to plunge into cold water to relieve his sufferings.

CALIBER; the interior diameter of the bore of any piece of ordnance, or the diameter of a shot or shell.

Caliber or *caliper compasses* are a sort of compasses with arched legs, used in the artillery practice, to take the diameter of any round body, particularly of shot or shells, the bore of ordnance, &c. The instrument consists of two thin pieces of brass, joined by a rivet, so as to move quite round each other. It contains a number of tables, rules, &c., connected with the artillery practice.

CALICO; a cotton cloth, which derives its name from Calicut, a city of India, from which it was first brought. In England, white or unprinted cotton cloth is called *calico*. Calico printing is a combination of the arts of engraving and dyeing, and is used to produce upon woven fabrics, chiefly of cotton, a variety of ornamental combinations, both of figure and colour. In this process, the whole fabric is immersed in the dyeing liquid; but it is previously prepared in such a manner, that the dye adheres only to the parts intended for the figure, while it leaves the remaining parts unaltered. In calico-printing adjective colours are most frequently employed. The cloth is prepared by bleaching, and other processes, which dispose it to receive the colour. It is then printed with the mordant, in a manner similar to that of copperplate-printing, except that the figure is engraved upon a cylinder instead of a plate. The cylinder, in one part of its revolution, becomes charged with the mordant mixed to a proper consistence with starch. The superfluous part of the mordant is then scraped off by a straight steel edge, in con-

tact with which the cylinder revolves, leaving only that part which remains in the lines of the figure. The cloth then passes in forcible contact with the other side of the cylinder, and receives from it a complete impression of the figure in the pale colour of the mordant. The cloth is then passed through the colouring bath in which the parts previously printed become dyed with the intended colour. When it is afterwards exposed and washed, the colour dis appears from those parts which are not impregnated with the mordant, but remains permanently fixed to the rest. When additional colours are required, they are printed over the rest, with different mordants, suited to the colour intended to be produced. This secondary printing is generally performed with blocks, engraved in the manner of wood-cuts, and applied by hand to the successive parts of the piece. See WEAVING.

CALK; to drive a quantity of oakum into the seams of planks, to prevent the entrance of the water. After the oakum is driven in, it is covered with melted pitch or resin, to preserve it from the action of the water.

CALLUS is a preternatural hardness, whether carneous or osseous. The new growth of bony substance between the extremities of fractured bones, by which they are united, is an instance of the latter. External friction or pressure produces the former, as in the hands of labourers, and the feet of persons who wear tight shoes.

CALMS, REGION OF. In the Atlantic Ocean, between the tropic of Cancer and lat. 29° N., and on the confines of the trade-winds, between 4° and 10° N. lat., calms of long duration prevail; and hence these tracts are called the *calm latitudes*, or the *regions of calms*. In the latter tract particularly, these perpetual calms are accompanied by a suffocating heat, by thunder-storms, and floods of rain, so that it is sometimes called the *rainy sea*. The only winds that occur are sudden squalls of short duration and little extent. In these calms the provisions are corrupted, the seams open, and the stagnant air breeds disease. When a ship is in this positon, if the currents set in towards rocks, and the sea is too deep to cast anchor, her destruction is almost inevitable. In the Mediterranean, where there are no tides, *dead calms* are more common than in the open ocean; but they are often the presages of approaching storms.

CALOMEL, or mild muriate of mercury, is a very important article in the *pharmacopœia*. The preparation may be thus described: If four parts of corrosive muriate of mercury be well mingled by trituration with three of mercury, they assume the form of a gray powder. If this powder be sublimed in a sand heat, either from an ordinary phial, or from a bolthead, a white crystalline sublimate is obtained. This product is a combination of oxide of mercury with muriatic acid. It is much used in medicine, especially for biliary diseases.

CALORIC is the name given in chemistry to that agent which produces the phenomena of heat and combustion. It is hypothetically regarded as a subtile fluid, the particles of which repel one another, and are attracted by all other substances. It is imponderable, and, by its distribution in various proportions among the particles of matter, gives rise to the three general forms of gas, liquids, and solids. The particles of water, by losing caloric, have their cohesion so much increased, that they assume the solid form of ice; by adding caloric, they again become fluid; and by a still farther addition, they are converted into vapour.

Caloric exists in two different states—*free* or *uncombined*, and *in a state of combination*. In the former condition, it creates the sensation of heat, and produces expansion in other bodies. The power which any body has of exciting the sensation of heat, and occasioning expansion, is understood by the expression of its *temperature*. This is supposed to vary with the quantity of free caloric in a given quantity of matter; a high temperature being ascribed to the presence of a large quantity of free caloric, and a low temperature to that of a small quantity. We are ignorant, however, of the extremes of temperature, and may compare it to a chain, of which a few of the middle links only, are exposed to our observation, while its extremities are concealed from our view.

The *expansion of bodies* is one of the most universal effects of an increase of temperature. This increase in bulk, however, is not the same in all bodies. The same increase of temperature causes liquids to expand more than solids, and aëriform bodies much more than either. On this principle are constructthe various instruments for measuring the temperature; since the degree of expansion produced by caloric bears a sufficient proportion to its quantity to afford us the means of ascertaining it with tolerable accuracy. Our senses, it is obvious, are quite inadequate to afford us this information; for we compare our sensations of heat, not with any fixed or uniform standard, but with those sensations which we have had immediately previous. Hence, the same portion of water will feel warm to a hand removed from contact with snow, and cold to another hand which has been heated before the fire. To convey precise notions of temperature, therefore, we are obliged to describe the degree of expansion produced in some one body which has been previously agreed upon as a standard of comparison. The standard most generally adopted is quicksilver, which is contained in a glass ball, terminating in a long narrow tube. This instrument is called a *thermometer*.

If quicksilver, or, indeed, any other substance except the gases, suffered equal exapansion by equal increments of the calorific power, then this instrument would be perfect; but the same increase of bulk is not effected in the same liquid or solid, at all temperatures, by adding similar quantities of heat; for bodies expand, by equal increments of caloric, more in high than in low temperatures, because the force opposing expansion is diminished by the interposition of caloric between the particles of bodies; and, therefore, when equal quantities of caloric are added in succession, the last portions meet with less resistance to their expansive force than the first. In gases, on the contrary, which are destitute of cohesion, equal increments of heat appear to be attended with equal augmentations of bulk. The *tendency to an equilibrium* is a characteristic of free caloric.

Any number of different bodies, unequally heated, when exposed in an apartment to the same temperature, gradually arrive to an equality of temperature. It is in obedience to this law, that we experience the sensations of heat and cold when we touch bodies which are warmer or colder than ourselves. There exists much diversity in the rapidity with which

different substances attract caloric when in contact with a body in which it is accumulated. Common air and gases abstract it but tardily, while wood, stones, and metals acquire it more rapidly. According to their power of conducting it off under these circumstances, bodies are divided into *conductors* and *non-conductors* of caloric; and, in general, the power of conduction varies with the densities of bodies. But this tendency of caloric to an equilibrium is not established solely by the agency of intermediate bodies or communication. A part of it moves through the atmosphere, like light, in right lines, and with immeasurable velocity, and has therefore been called *radiant caloric*. The comparative quantites lost by radiation and by conduetion may be approximated by observing what time it takes to cool any body through the same number of degrees in air and *in vacuo*. Thus Doctor Franklin imagined he had ascertained that a body which requires five minutes to cool *in vacuo*, will cool in air, through the same number of degrees, in two minutes. Count Rumford's experiments, with a Torricellian vacuum, give the proportions of five to three.

Radiant caloric passes only through transparent media, or free space. When, in its passage, its rays impinge upon the surface of a solid or a liquid substance, they are either reflected from it, and thus receive a new direction, or they lose their radiant form altogether, and are absorbed. In the latter case, the temperature of the receiving substance is increased; in the former it is unchanged. The nature of the surface of a body has been found to influence powerfully both the radiation and absorption of caloric. The energy of calorific emanation from a cubical tin vessel, coated with different substances, and containing warm water (as determined by the differential thermometer of Leslie), gave, with a covering of

Lampblack, ...	100
Isinglass, ...	75
Tarnished lead, ...	45
Polished iron, ...	15
Tin-plate, gold, silver, or copper,	12

Similar results were obtained simply by noting the rates of cooling in vessels of similar shapes and capacities with various surfaces. Useful lessons have been derived from these discoveries. Tea and coffee-pots, which are intended to retain their heat, are made of bright and polished metals; and steam-pipes, intended to convey heat to distant apartments, are kept bright in their course, but darkened where they reach their destination. The power of different surfaces to absorb caloric was found, by coating one of the bulbs of the differential thermometer successively with different substances, and presenting it to an uniformly heated substance, to follow the same order as the radiating or projecting quality.

With regard to *combined caloric*, it has been shown that solids, during liquefaction, imbibe a quantity of caloric, which ceases to be obvious, both to our senses and to the thermometer. The same is also true of solids and liquids in their conversion into vapours or gases; a portion of caloric, which is essential to the elasticity of the new product, ceases to become apparent. Whenever this effect takes place, *cold* is said to be produced; by which we are only to understand the passage of caloric from a free to a latent form. The reverse of these phenomena has also been satisfactorily established; viz. when the density of bodies is increased, either by chemical or mechanical means, caloric is evolved. For example, a high temperature is produced by mingling cold sulphuric acid and water; metals become intensely heated by the augmentation of their density through hammering; liquids, by becoming solids, or gases by conversion into liquids also evolve caloric. A pound of water, condensed from steam, will render 100 pounds of water at 50° warmer by 11°; whereas, a pound of boiling water will produce the same rise of temperature in no more than about 13.12 pounds; and since steam and boiling water affect the thermometer in the same manner, this effect can be produced only from the existence of a much greater quantity of caloric in the former than in the latter.

The *sources of caloric* are six; viz. the sun's rays, combustion, percussion, friction, the mixture of different substances, electricity, and magnetism.

CALORIMETER; an instrument to measure the capacity of a body for caloric, or its specific caloric. The thermometer measures merely the variations of temperature, or sensible heat. The body in the calorimeter is placed in the innermost of three concentric vessels, the two outer ones containing ice; the quantity of water produced by the cooling of the body a given number of degrees, determines its specific caloric. This instrument was invented by Lavoisier and Laplace. In the calorimeter invented by Rumford, water is used; the capacity of the body is determined by the number of degrees which the temperature of the water is raised, in cooling the body a given number of degrees.

CALORIMOTOR. See GALVANIC BATTERY.

CALX; properly lime or chalk; but the term is more generally applied to the *residuum* of a metal or mineral which has been subjected to violent heat, burning or calcination, solution by acids, or detonation by nitre, and which is or may be reduced to a fine powder. Metallic calces are now called *oxides*. They weigh more than the metal from which they are produced, on account of the oxygen which they have obsorbed.

CAMAIEU. This term is used for a painting wherein there is only one colour, and where the lights and shades are of gold, wrought on a golden or azure ground. When the ground is yellow, the French call it *cirage*, when gray, *grissaile*. This kind of work is chiefly used to represent *basso-relievos*. See CAMEO.

CAMBLET, in *Commerce*; a stuff sometimes of wool, sometimes of silk, and sometimes hair, especially that of goats, with wool or silk; in some, the warp is silk and wool twisted together, and the woof hair.

The true, or Oriental camblet, is made of the pure hair of a sort of goat frequent about Angora, and which makes the riches of that city, all the inhabitants being employed in the manufacture and commerce of camblets.

CAMBRIC, in *Commerce*; a species of linen made of flax, very fine and white; the name of which was originally derived from the city of Cambray, where they were first manufactured.

CAMEL, in *Mechanics*; a machine used in Holland and St. Petersburg for lifting ships over shallow bars. De Witt invented these machines, and Peter the Great introduced them into Russia. A camel is composed of two separate parts, the insides of which

are shaped so as to embrace the hull of a ship on both sides. Each part has a cabin, with many pumps and plugs. They are fastened to the vessel underneath, and entirely enclose its sides and bottom. They are then towed to the bar, and are sunk with the vessel, by taking out the plugs. The water being now pumped out, the camel lifts the vessel, and the whole is towed over the bar.

Camelopardalus, in *Astronomy*; a new constellation of the northern hemisphere, described by Hevelius, consisting of 32 stars, first observed by him, situate between Cepheous, Cassiopea, Perseus, the two Bears, and Draco, and containing 58 stars in the British Catalogue.

Cameo, or Camaieu; in the proper sense, a gem engraved in *relievo*. The ancients generally used the onyx for this purpose. At first, such onyxes, and afterwards all gems carved in relief, were called *cameos*. They were carved according to the layers of the stone, so that the ground should be of a different colour from the figure in relief. One of the most famous cameos is the onyx at present in Paris, called the *Apotheosis of Augustus*, 1 foot high and 10 inches wide.

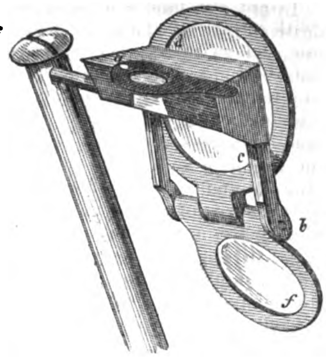
Camera Lucida. This optical instrument, in the hands of an experienced draftsman, is admirably fitted to save time, and supply the place of a knowledge of perspective. Generally speaking, however, the *camera lucida* is laid aside as soon as it is taken in hand, as much practice is essential to its useful application.

If a piece of plain glass be fixed at an angle of 45 degrees with the horizon, and if, at some distance beneath there be a sheet of paper laid horizontally on a table, a person looking downwards through the glass, will see an image of the objects situated before him; and as the glass which reflects the image is also transparent, the paper and pencil will be seen at the same time with the image, so that the outline of the image may be traced on the paper. The image is an *inverted* one. This is the simplest form of the instrument, and may be constructed extemporaneously by fixing on a stand a plain transparent glass, with its surfaces ground parallel, or a piece of Muscovy glass, at an angle of 45 degrees with the horizon; a card, with a small hole in it, will serve as a sight for keeping the eye steady in one situation, whilst the pencil is tracing the image.

If there be a plain object at an angle of 22½ degrees with the horizon, and a piece of plain transparent glass be placed near it, at an angle of 22½ degrees with the vertical, the rays from the object will be twice reflected before they reach the eye, and consequently on looking down through the transparent glass, an *erect* image is seen, and the pencil may be drawn over the outlines of this image so as to leave a perspective representation on the paper.

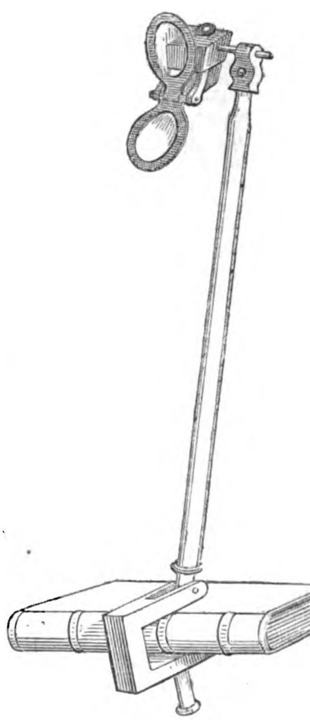
As the image and pencil are at different distances, they cannot be both seen in the same state of the eye. To remedy this inconvenience, a convex glass is used, of such focus as to require no more effort than is necessary for seeing the distant objects distinctly. By means of this lens, the image will appear as if it were placed on the surface of the paper.

Those whose eyes are adapted to seeing near objects alone, will not derive advantage from the use of a convex glass, but will require a concave glass to be placed in the course of the rays from the object to the reflecting surface.



In the accompanying figure *d f* are glasses placed in the above-mentioned situation; they are so disposed as to be turned at pleasure into their proper place at the joint *b*. Persons whose sight is nearly perfect, may use either the concave glass placed before the reflecting surface, or the convex glass placed between the paper and the eye.

In the actual construction of the instrument, a prism is used instead of a mirror and a plain glass. The rays from the object fall upon the surface of the prism. This surface is inclined 22½ degrees to the horizon. The refractive power of the glass allow snone of the rays in this position to pass out; they are all reflected. The eye cannot see the pencil through the prism as it does through a plain glass; therefore, in order that the pencil may be seen, the eye must be so placed that only a part of the pupil may be above the edge of the prism, and then the reflected image will be seen at the same time with the paper and pencil. There is a small piece of brass perforated with a hole, and moving on the centre at *a*; this serves to keep the eye in one position, that the image may be steady, and also to regulate the relative quantities of light to be received from the object and from the paper.



The annexed figure shows the instrument on its stand, and clamped to a book. The joint by which the prism is attached to the stand is double. The whole instrument packs in a small box. This instrument serves for drawing objects of all forms, and consequently also for copying lines already drawn on a plain surface. If it is required that the copy shall be of the same size as the drawing, the distance of the drawing from the prism should be the same as the distance of the paper from the eye-hole. No lens will be necessary in this case, because the image and the paper being both at the same distance, coincide.

In order to have a reduced copy of a drawing, the drawing is to be placed at a distance from the prism greater than the distance of the paper from the eye-hole. If the distance is twice as great, a copy will be obtained, in which the lines will be of one-half the size of the lines in the original, and so in proportion to other distances. A lens is necessary, that the eye may be enabled to see at two different distances; and, in order that one lens may serve, the distance between the eye-hole and the paper should be variable; on that account the stand is susceptible being lengthened or shortened.

Camera Obscura (dark chamber), is either a closed room, in which the light can fall only through a small aperture, or an optical box, in which exterior objects are represented on a smaller scale. It is used for amusement, or for drawing landscapes and scenery, though what is gained in rapidity and ease of execution is lost in the dimness of the colouring. (For the theory of this instrument, see Optics.)

Cames are slender rods of cast lead, of which glaziers make their turned or milled lead, for joining the panes or quarrels of glass.

Camp means, generally, the place and order of tents or huts for soldiers in the field. In modern times, a difference is made between *camp* and *bivouac*, the former signifying the residence of an army resting in tents; the latter, the situation of one which dispenses with them, and remains either entirely in the open air, or, where time allows it, in huts built of branches, &c. On the continent of Europe, tents are abolished, and the name of *camp*, therefore, is seldom used there at present.

Camps, of course, are of very ancient origin, since almost all nations, in their infancy, lived as nomades, dwelling in tents; as is the case with many tribes in Asia and Africa at the present day, e. g., the Arabs. The Romans, probably, first carried the art of encampment to a high degree of perfection, on account of their many wars in distant and thinly settled regions, where their large armies found no cities to quarter in. Cæsar and several other Roman authors give us much information on their way of constructing a camp, which they improved in strength and convenience, according to the time they were stationed in it, and which at the same time, the want of fortresses obliged them to make, in some cases, the points of their military operations. From such camps, it is well known, many cities orginated, as Cologne on the Rhine, Treves, Cambridge, Bristol, and many others. It is a fact of much interest, that the military art, after so many changes in tactics, and in the principles of strategy, again resorts to something similar to these fortified camps of the ancients, as in very recent times, it has been thought advisable, besides providing fortresses, properly so called, to strengthen certain large cities on the chief roads, partly in order to defend them against the first attack of the enemy, and to prevent his possessing himself easily of the important resources which they afford, but chiefly to give to retreating armies rallying points, able to furnish support to numerous soldiers. They are also points of assembly for the militia. Thus the Prussians fortified the large city of Cologne. Of all the European armies, the English are the only ones, we believe, who make use of tents, and therefore have camps, in the narrower sense of the word. It is to be observed, that camps have become slighter and simpler with the progress of the military art. The camps of the Turks, or other Asiatic nations, are extremely cumbersome, in comparison with the light bivouac of the Europeans, from which, at any moment, the whole army can rise in arms prepared for battle.

Campaign generally denotes the season during which armies keep the field. It also means an extensive level country. Formerly, when war was not carried on with so much impetuosity as at present, campaigns lasted only during the warmer months; and towards winter, the troops went into winter-quarters, when the officers of the opposing armies often met very amicably at balls and other entertainments; but of late, armies have kept the field through the winter, till a decisive victory has been gained. Thus, the allies, in the winter of 1813—14, followed the French over the Rhine; some battles were fought in January and February, and the armies remained for several months without roof or tent, in the open air of a cold winter.

Campanile; a detached tower, in some parts of Italy, erected for the purpose of containing bells. Several of them have deviated considerably from the perpendicular, in consequence of their great height and narrowness of base. The campanile of Pisa, called *Torre Pendente*, or Hanging Tower, is the most remarkable of these. Its height is 150 feet, and it inclines nearly 13 feet from the perpendicular. The tower consists of eight stories, each of which is surrounded by columns.

Camphor is a white, resinous production, of peculiar and powerful smell, not unlike that of rosemary, and is extracted from two or three kinds of trees of the bay tribe, that grow in the islands of the East Indies and China. Of these, the principal is the *laurus camphora* of Linnæus. It is of considerable height, much branched, and has spear-shaped leaves, with nerves, of a pale yellowish-green colour on the upper side, and bluish-green beneath. The flowers are small, white, and stand on stalks which issue from the junction of the leaves and branches. Camphor is found in every part of the trees; in the interstices of the perpendicular fibres, and in the veins of the wood, in the crevices and knots, in the pith, and in the roots, which afford by far the greatest abundance. The method of extracting it consists in distilling with water in large iron pots, which serve as the body of the still, with earthen heads fitted to them, stuffed with straw, and provided with receivers. Most of the camphor becomes condensed in the solid form among the straw, and part comes over with the water. Its sublimation is performed in low flat-bottomed glass vessels, placed in sand, and the camphor becomes concrete, in a pure state, against the upper part, whence it is afterwards separated with a knife, after breaking the glass. Numerous other vegetables are found to yield camphor by distillation. Among them are thyme, rosemary, sage, elecampane, anemone, and pusatilla. A smell of camphor is disengaged when the volatile oil of fennel is treated with acids; and a small quantity of camphor may be obtained from oil of turpentine by simple distillation, at a very gentle heat. Camphor has a bitterish, aromatic taste, is unctuous to the touch, and possesses a degree of toughness which prevents it from being pulverised with facility, unless a few drops of alcohol be added, when it is easily reduced to a powder. It floats on water, and is exceed-

ingly volatile, being gradually dissipated in vapour if kept in open vessels. At 288° Fah. it enters into fusion, and boils at 400° Fah. It is insoluble in water, but is dissolved freely by alcohol, from which it is immediately precipitated in milky clouds, on the addition of water. It is likewise soluble in the fixed and volatile oils, and in strong acetic acid. Sulphuric acid decomposes camphor, converting it into a substance like artificial tannin. With nitric acid, it yields a peculiar acid, called *camphoric acid*. This acid combines with alkalies, and forms peculiar salts, called *camphorates*. They have not hitherto been applied to any useful purpose. As an internal medicine, camphor has been frequently employed in doses of from 5 to 20 grains, with much advantage, to procure sleep in mania, and to counteract gangrene. In large doses, it acts as a poison. Dissolved in acetic acid, with some essential oils, it forms the aromatic vinegar. It promotes the solution of copal; and from the circumstance that its effluvia are very noxious to insects, it is much used to defend subjects of natural history from their ravages. In a crude state, camphor is formed into irregular lumps, of a yellowish-gray colour, somewhat resembling nitre or bay-salt. It is imported into Europe in canisters, and the refining of it was long kept a secret by the Venetians. The Dutch have since performed this work; and large quantities of camphor are now refined by some of the English and American chemists. For carpenters' work, the wood of the camphor-tree is much used. It is light and durable, and, in consequence of long retaining its aromatic smell, is not liable to be injured by insects. Plants of the camphor and cinnamon trees were captured by Admiral Rodney, in 1782, and afterwards carried to Jamaica, and propagated there. The camphor-tree which grows very abundantly in the western parts of Japan, is a different species from that found in the islands of Sumatra and Borneo, with which we are principally acquainted. Camphor was formerly in great repute as a medicine, but at present its virtues are less highly rated. It is a cordial and stimulant of a decidedly heating character, and is therefore improper in all fevers, unless the system is very low and weak. In such cases, if combined with nitre and other cooling articles, it is sometimes an excellent diaphoretic: but in fevers in general, it is an article rather to be avoided. It was once, however, and is now, in some parts of Europe, thought to be one of the best medicines in fever of almost all sorts; but it is an article that could well be dispensed with in common practice. As a domestic cordial and medicine, it is perhaps more used than any other, being still, in families, a panacea for all ailments of the smaller sort.

CANAL. A canal, in navigation, is an artificial channel for transportation by water. The first inquiry in the project of such a work, accordingly, relates to the amount of transportation that will be accommodated by the route proposed, at some given rate of tolls (for the quantity will be in some degree influenced by that rate). If the project be a mere speculation, or investment of capital by individuals for the sake of income, its expediency will be determined by the net amount of annual tolls it will probably yield; which ought, in this view of the matter, to be equal to the ordinary rate of interest. But the general utility or public expediency of a project of this sort is not determined wholly by this mode of calculation; for, in this view, we must look at the indirect advantages, such as the increased value of lands on the borders of the canal, the increased profits of other works connected with or affected by the one proposed; as in the case of the smaller branches of internal navigation in England, many of which, as will be seen by referring to the subjoined list, are not very productive investments, but doubtless contribute to the large income of the great lines of transportation between the principal towns, as London and Liverpool, by increasing the amount of goods that pass along those lines. To determine the general public utility of one of these smaller branches, therefore, we must estimate not only the increased value which it gives to coal mines, stone quarries, forests, &c. on the borders, but also its effects in enhancing the value of other canals. But a work of this sort may be, on the whole, of public utility, although an absolute income, in consequence of the investment, can nowhere be traced, but only a reduction of the cost of some article of general use, by means of a diminution of the labour, the number of days' or hours' work, necessary to furnish the article, at any place. Thus the proprietors of the Duke of Bridgewater's Canal are under obligation to supply the inhabitants of Manchester with coals at the rate of four-pence for 140 pounds, which is a great benefit to the inhabitants of that town. This is one of the advantages of this work, which should be taken into the account in estimating its public utility. Another beneficial consequence of any great improvement of this description, as well as those of other kinds, often is to promote some species of arts: for instance, a canal may promote agriculture, horticulture, &c., by irrigation or opening a market. In determining on any canal project, then, as well as in estimating its utility, these various circumstances are to be taken into consideration. The motives, whether of public utility or private emolument, or a union of them both, being sufficient to induce to the undertaking, the next things to be considered are, the obtaining of an adequate supply of water, the particular route to be taken, and the mode of construction. On these subjects, the reader is referred to the treatises more particularly relating to them. The remainder of the present article will be devoted to a general account of some of the most considerable works of this sort in various parts of the world.

CANALS OF EGYPT. Egypt has been celebrated for its canals from the earliest periods of history. The principal are the *Canal of Alexandria*, between that city and Rosetta and the Nile; that of *Jessuf*, on the western bank of the Nile, and parallel to it; and that of the *Red Sea and Nile*, across the isthmus of Suez. The existence of this last, though a subject heretofore of some discussion, is now established beyond doubt. It was begun by Necho, son of Psammeticus, about 616 B. C., and the work was continued by Darius Hystaspes, but was afterwards abandoned, from fear of inundating a great part of Egypt, which is supposed to be lower than the surface of the Red Sea. The work was, however, resumed, and completed nearly a century afterwards, about 521 years before the Christian era, by Ptolemy II.; but a current from the Red Sea upon Egypt was prevented, it seems, by a barrier or bank across the canal; or a part of the route may have been left not excavated. This dam, if narrow, might have been passed by boats on inclined planes, after the Chinese method,

or otherwise; but it seems to be more probable that boats did not pass between the canal and the Red Sea, but that the cargoes were carried by land across the intervening barrier, or portion of ground not excavated, and reshipped. Herodotus says this canal was of four days' navigation, and wide enough to admit of four vessels to pass abreast. Strabo says it was 100 cubits wide, and of sufficient depth for large vessels. The breadth would probably vary very much, as does that of the canal of Alexandria; for if it was made, for any considerable part of the distance, by embanking, instead of excavating, additional breadth might be given without increasing the expense of construction; and if navigated by sailing-vessels, like the canal of Alexandria, the additional breadth would be convenient, though not maintained through the whole route.

The *Canal of Jessuf* leaves the Rosetta outlet of the Nile, near Rhameneh, passes a little south of Demanhour (the ancient *Hermopolis Parva*), and thence by the north-east shore of the lake Mareotis to Alexandria. Two branches pass off in a north-west direction, and one in a southwardly, which communicates with the lake Mareotis. This canal is navigated by sailing-vessels, being in most parts of a convenient breadth for this purpose, though at its entrance from the Nile by its new channel, it is only 19½ feet wide. The old entrance, a little north of the new, is not used, on account of the height of the banks, which intercept the wind. Afterwards, at the village of Lemedis, it spreads to the breadth of about 55 yards, and keeps this breadth for 2½ leagues, where the banks are 13 feet above the bottom of the canal, and 10 above the surface of the ground. Passing over 2 leagues more, towards Alexandria to Gabel, the breadth is contracted to 22½ yards. It continues of about this breadth for 4 leagues, and is very regular. Beyond Leloha, it widens, varying in the first half league from 109 to 273 yards in breadth. Near Beda, it is 55 yards wide, and the banks 23 feet high. Passing on towards Alexandria, the country sinks by degrees, until the bottom of the canal is on a level with the adjacent territory, and then rises above it, the canal being here formed by embankments; but, for a league before arriving at Alexandria, the ground rises again, so that the canal is here formed by an excavation in the ground. It passes very near the lake Aboukir, on the left, in the course we have been following, and is separated from it, near the western extremity of the lake, only by a wall about 20 feet in thickness. The water must rise 13 feet above the lowest state of the Nile to enter the *Alexandria Canal;* and at high water in the Nile, the water in the canal is about 2 feet deep on an average. The distance, in a straight line, from Rhameneh to Alexandria, is about 15 leagues, but by the course of the canal, 20. The navigation of this canal continues only about 20 or 25 days in the year, during the highest water of the Nile. The French, when in Egypt, were enabled to navigate this canal for six weeks by clearing away about 18 inches of mud near Rhameneh, at the eastern extremity. This canal, which now passes through ruins and deserts, and is navigable for only a few days of the year, was, as late as the fourteenth century, bordered by a wealthy and populous territory, and, in the time of the Roman and Greek empires, was the channel of an extensive transportation.

CANALS OF CHINA. The Chinese seem to have a more extensive inland canal navigation than any other nation, if not greater than that of all other nations. The general course of the rivers is from west to east, the principal of which are the Yang-tse, or Kiang-keo, to the south, the course of which is said to be 2000 miles, and its breadth 2½ miles at a distance of 100 miles from its mouth; and the Yellow River, to the northward, which is represented to be still longer. These two rivers pass into the sea, within 100 miles of each other, though they are more than 1000 miles apart in the interior of the country. The artificial channels of navigation pass in a northerly and southerly direction across the territory lying between the natural streams, thus making lines of communication between these principal rivers and their various branches, which form the natural channels of transportation in the easterly and westerly directions. As these canals pass over the summits of the intermediate territories between the great streams, the different parts of the canals must be upon different levels, and there must, accordingly, be some means for boats to pass from one level to another, which they do mostly by means of inclined planes and rollers, over which they are drawn by men. The ascent and descent, at some of these planes, is 15 feet. The banks of the canals are, in many instances, lined with freestone, and contain sluices to let the water off for irrigating the country and supplying the towns; and in many parts, also, they are beautifully ornamented with trees. The barque in which Le Compte passed from Nimpo on a canal, was 70 feet long and 16 feet broad. The management, repairs, and extension of the canals is a very important branch of the internal economy of the empire, and the description and history of these works is said to occupy 40 volumes; which does not, however, give us a very definite idea of the extent of these records, as we are not told the size of these volumes. Some of the most extensive of their canals have been in operation about 2000 years, having been completed 80 years before the Christian era; and, about A. D. 605, it is said there were completed in the empire 1600 leagues of canal.

The *Imperial Canal*, and the continuation of the line of transportation between Pekin and Canton, of which that forms a part, is most frequently spoken of, though the distance of the whole route is variously stated. Malte-Brun, in his Geography, states it at 1660 miles, but it is stated by others at 920. The navigation over this route occupies about three months. The part of this line called the *Imperial Canal* is said to be about 500 miles in length from the vicinity of Pekin to the Yellow River, which it meets about 25 leagues from the sea, where the river is about a mile wide and 9 or 10 feet deep. This canal is called the *Imperial*, from its being navigated only by the emperor's boats, which Le Compte estimates at 1000 of 100 tons burthen each. Between the Yellow River and Canton, the navigation is interrupted, for about 30 miles, by a mountainous district, causing a portage of that distance.

CANALS OF ITALY. In ancient Italy, besides the *Canal of the Pontine Marshes*, intended as a drain, and used also for navigation, the region about the mouths of the Po was intersected by the *Fossa Augusti*, *Fossa Philistina*, and numerous other canals. It was in Italy that the great improvement, in modern canals, over the ancient and those of China, was first introduced, in 1481, by the construction of locks and

sluices to pass boats from one level to another. It was the invention of two engineers of Viterbo, brothers, whose names have not been handed down. This improvement was soon after adopted in the Milanese territory, under the direction of Leonardo da Vinci, the famous painter, who was also celebrated as an engineer. Inland navigation became so important, that the Italian governments paid great attention to it, and enacted many regulations on the subject, and numerous treatises were published on the construction of locks and the art of making and managing canals. The following are some of the principal canals of modern Italy:—The *Naviglio Grange*, between Milan and the river Tesino, 15 miles in length, 130 French feet broad at the surface, and 46 at the bottom. It was extended to Milan in 1257, and enlarged, in 1269, with a branch of about 11 miles in length, from Abiato southward. The *Martesena Canal* branches off from the right bank of the Adda, near Concessa (ancient *Trizzo*); is 24 miles in length and 33 feet in breadth, and is raised, in some places, by walls and embankments 110 feet above the level of the river. In 1497, five locks were introduced into this canal. The *great canal of Tesino* terminates at Milan. The *Muzza Canal* is drawn also from the river Adda, near Cassano, and re-enters the river at Castiglione, 40 miles distant.

In *Piedmont* are the *Naviglio d'Inéa*, 38 miles in length, uniting the Dora Baltea and the Sessia, with a branch of 13 miles, to the Gardena River; and a canal of 27 miles from Dora Baltea, a little above the falls of the Po, which, passing Trino, unites with the Po four miles below Casal. These two canals are parallel to the Po, and substitutes for it. There are three other short canals in this territory.—In the *Duchy of Mantua* is the *Fossa Puzzola*, 15 miles in length, from the Mincio to the Tartaro, and the *Canal of St. George*, 7 miles long, branching to the Lake of Mantua; also the *Montanaro*, 8 miles from the same lake to the Po, at Borgo Fute; the *fossa Maestra*, 5 miles from Ozoma to the *Canal Montanaro;* and the *Fossero*, from the Mincio, 7 miles.—In the *Duchy of Modena* is a canal 16 miles in length, from Secchia by Modena to Panaro, which has several branches, one 5 miles long.—In the *papal territory* is the *fossa Rangone*, parallel to the Panaro, from which a branch passes off by Conte to Po Mort or Po di Jerana, and the *Canal Di Giovanni Niginales*, 22 miles long. From Bologna to Ferrara is the *Canal Di Naviglio*, 24 miles long, and terminating in the great marshes. There are, besides, many short branches of the canals already mentioned, as well as locks and channels for passing rapids in the navigable rivers.

Canals of Russia. The canals of Russia began with Peter the Great, who had observed their useful effects in Holland. He commenced three. The *Canal of Ladoga*, begun by him A. D. 1718, and finished by the Empress Anne, is 67½ miles long, from the Volk to the Neva, 70 feet broad, and the water 7 feet deep in summer, and 10 in winter.—The *Canal of Vishnei-Voloshólk*, completed under Peter the Great, but much improved afterwards by Catharine, forms a communication by water between Astracan and Petersburg, or between the Caspian and the Baltic, which is effected, as will be seen by referring to the map, by passing from the Caspian up the Wolga, then turning into the river Ivertza; leaving which, the canal passes over to the river Schlina, which flows towards the Baltic into the Lake Martina, from which flows the river Mista, which, after a course of 234 miles, discharges itself into Lake Ilmen, from which issues the Volk, that runs 130 miles, and empties into the lake Ladoga, which again gives rise to the Neva, that discharges itself into the Baltic at Petersburg; so that these three rivers are, in fact, the same stream, passing through three lakes in its course. It is said that 3485 barques have passed through this canal in one year. There are many other canals in Russia, which we have not space to describe. The canals and rivers supply the channels of a very extensive inland navigation in Russia; so that goods may be transported, by rivers and canals, from the frontiers of China to Petersburg, a distance of 4472 miles; and the line of navigation from Astracan to that capital is 1434 miles.

Canals of Sweden. Canals were early opened in Sweden, and the improvement of the inland navigation has always been a subject of great interest to the government. Among the modern canals of this country is that of *Stromsholm*, 60 miles long, the descent 336 feet, the number of locks 25, breadth 18 feet, and depth 4 feet 4 inches.—The *Kindac Canal* and the *Gotha Canal*, intended to open a communication between the lake Wenner and the Baltic, have been commenced under the superintendence of the English engineer Mr. Telford.—The *Canal of Trolhatta* makes a navigable channel round the rapids of Trolhatta, in the river Gotha, consisting of successive cascades, one of 60 feet in height, and, in all, 114 feet, and situated N. E. of Gothenburg, about 45 miles. The project of constructing works, by which to pass these rapids, was long contemplated, and finally accomplished in 1800. These rapids interrupted the navigation of the Gotha for about two miles; and the difficulty of making a canal past them was owing to the banks being bold and rocky, as is usual at falls of such extent. They are now passed by nine locks, mostly excavated out of solid rock. This is considered a gigantic work, and was executed by a private company, for their own emolument, as well as the public benefit.

Canals of Denmark. The principal canal in this country is that of *Keil*, which commences about three miles north of Keil, and passes 20½ miles across the Duchy of Holstein to the river Eydar, which running by Rendsburg, falls into the German Ocean at Jonningen. The Keil Canal thus opens a communication between the two seas. It was begun in 1777, and completed in 1785; is 100 feet broad at the top, 57 at the bottom, and the least depth of water is 10 feet. The descent from the summit towards the Baltic is 25½ feet, and towards the German Ocean 23 feet. It has 6 locks.

Canabs of Holland. This country, it is well known, is intersected in all directions, by canals, which serve for navigation in summer, and roads of ice in winter. The surface of the water in many of these canals, is above that of the surrounding country; the lands of which are drained by pumping the water up into the canals; for which purpose numerous windmills are scattered about the country and kept in operation.

Canals of Germany. The improvemt of inland navigation in Germany has been obstructed by the division of the territory into numerous small jurisdictions, which are in many respects independent of each other.—The canal between *Vienna* and *Neustadt* is 40 miles in length; and that of *Francis*, com-

pleted in 1802, between the Danube and Jeysse, is of the same length, and has three locks.—In Prussia are the *canals of Stecknitz, Planer, Potsdam, Finow, Muhlrose, Frederic William*, and the *Bromberg*. This last was constructed under Frederic the Great, by the engineer Breekenhaaff. It is 16 miles in length, has a descent of 67 feet, and nine locks.

CANALS OF SPAIN. Spain has done almost nothing towards improving its internal navigation. Some canals have been projected, but only a part of the *Arragon Canal* has been completed, consisting of two pieces of canal, both commencing at Navarre. Though this partial execution of the projected navigation has had a sensible effect in promoting the populousness, fertility, and wealth of the neighbouring territory, the work stands still; and there seems to be little prospect of the completion of the project.

CANALS OF FRANCE. The canals of France, next to those of Great Britain, are the most important in Europe, in respect to their extent and the difficulties overcome in their construction. The whole length of canal navigation in France is about 900 miles, or about one-third part of that of Great Britain.—*Canal of Briare*. The first important work of this kind, constructed in France, was the canal of Briare, called also, that of the *Loire and Seine*, because its object was to connect those two rivers. It was 37 years in execution, being begun in 1605, during the reign of Henry IV., and completed in 1642. It is 34½ miles in length. From the Loire, about a mile from Briare, it ascends along the river Frezee, by Ouzonne and Rogny, where are 7 locks; then by Chatillon and Montargis, and near Cepay meets the river Loing, which falls into the Seine. The locks of this canal, 40 or 42 in number, were the first executed in France. They vary from 124 to 164½ feet in length, and from 5 feet 4 inches to more than 13 feet in lift, and are according to some authorities, 14 feet 5 inches, or, according to others, $15\frac{16}{100}$ feet in breadth. The bottom of the canal is $25\frac{}{100}$ wide. It is supplied with water principally by lakes; one of the feeders, that of Privé, is 12 miles in length. The cost of this canal is estimated at 20,000,000 francs, or about 3,700,000 dollars, which, considering the difference in the value of money, is nearly equal to that of the Erie Canal of New York. It is important for the supply of provisions to Paris.—The *Canal du Midi*, or *Languedoc Canal*, makes a communication between the Mediterranean at the city of Cette, and the Atlantic Ocean at the mouth of the Garonne, passing through the province of Languedoc, and is supplied by the rivers Garonne and Gironde, and their tributaries. It was undertaken in 1664, 22 years after that of Briare was completed, and finished in 1680; being 148 English miles in length, from the coast of the Mediterranean to Toulouse, where it meets the Garonne; 64 feet wide at the surface of the water, and 34 or 35 feet at the bottom; rising, at the summit, 200 metres, or about 640 feet above tide-water, and having 114 locks, varying in lift from 4 to 12 feet, and navigated by boats 85 feet long, and from 17 to 19 broad, drawing 5 feet 4 inches of water, and of 100 tons burthen. The reservoir of St. Ferrol is situated at the summit-level, where a body of water more than five French leagues in length is accumulated, for the supply of the canal, from the streams falling from the neighbouring mountains. This reservoir and the basins at Castelnaudary cover 595 acres. The canal passes under a mountain at Beziers, by a tunnel of 720 feet in length, lined throughout with freestone—a kind of construction novel at the time when the canal was made, though now common. The canal is crossed by 92 road-bridges, and has 55 aqueduct bridges. It was completed under Louis XIV., under the direction of François Andreossi, as engineer. It is estimated to have cost 33,000,000 francs, or about 6,160,000 dollars; in comparing which with the cost of similar works in Great Britain and the United States, allowance must, as above suggested, be made for the difference in the value of money, the same nominal cost, in France, being a much greater actual cost in this comparison.

The *Canal of Orleans* was the next in order of time, having been begun in 1675, and completed in 1692, 12 years after that of Languedoc. It branches from the Loire, near to Orleans, 36 miles below the place where the canal of Briare meets that river, and joins the canal of Briare at Montargis, being 45 miles long. One object of its construction was to save the difficult navigation on the Loire, between Orleans and the junction of the canal of Briare with that river, and to open a shorter route of communication between the Lower Loire and Paris. It has 28 locks varying from 136½ to 177½ feet in length, and of lifts from 5 feet 4 inches to 12 feet 7 inches. From the Loire to the summit, the ascent is 98 feet 2 inches. The breadth is from 25 feet 7 inches to 32 feet, at the surface of the water, and the depth from 4½ feet when full, to 2 feet when lowest. The boats are from 96 to 102 feet long, and 18 feet 10 inches broad. The expense of its construction is stated at 8,000,000 francs, or about 1,500,000 dollars.

The *Canal of Loing* is a continuation of the navigation of that of Orleans, and the northern part of that of Briare, commencing from the northern extremity of that of Briare, and extending to the river Seine, terminating in the neighbourhood of Fontainbleau. It was completed in 1723, is 33 miles long, 44 feet broad at the surface, 34 at the bottom, and from 4 to 5 feet deep. The towing-path, on each side, is 6 feet 5 inches broad, outside of which, on each side, is an embankment, like the *levées* on the Mississippi, or the dykes of Holland, 3 feet high, 19 feet broad at the base, and 12 feet 9 inches at the top, to prevent the waters from overflowing during floods. The whole descent is 136 feet 8 inches, divided among 21 locks, which vary in lift from 4 to 7 feet, and in breadth from 15½ to 16. The cost is stated at 2,500,000 francs, or about 466,000 dollars. It was constructed about the same time with the canal of Orleans.

The *Canal of the Centre*, called also that of *Charolois*, and likewise a branch of the "Grand Navigation," completed in 1791, leaves the Loire at Dijon, follows the banks of the Arran, then the left bank of the Bourbonne, and passes by Parce, Genelard, Aire and Blanzey, to the lakes of Monschamin and Longpendu, which form the summit-level, the rise being 240 feet, by 30 locks, in 6300 metres. The summit-level is a distance of 3940 metres, whence the canal descends by the river Dheune, to St. Julian, where it crosses that river, and passes along the right bank by St. Benain, St. Leger, and St. Gilles, to Chagny, leaves the valley of the Dheune, and crosses towards the river Halia, which it follows to its junction with the Soane at Chalons, the descent from the summit being 400 feet by 50 locks, in a distance of 47,000

metres; the whole length of the canal being about 71 miles, the breadth, at the surface of the water, 48 feet, at the bottom 30 feet, the depth of the water 5½ feet, the length of each lock 100 feet, and its breadth 16. The cost of this canal is stated at 11,000,000 francs, or about 2,060,000 dollars.

The *Canal of St. Quinton* unites the Scheldt with the canal of Flanders. It was projected, in 1727, by the military engineer Devieq, but not constructed until 1810. The original plan, which has been very nearly followed, was to proceed from Maquincourt, near the Scheldt, to Mount St. Martin, there pass through a tunnel 3440 toises, or a little more than 3¾ miles long; then follow the valley of Bellinglise and Haut Court to the heights of Tronquoy; there pass through a tunnel 700 toises, a little more than ¾ of a mile in length, coming out at Ledin; making the distance of the summit-level 7090 toises, or a little over 8 miles, of which 2950 are open, and 4140, or more than 4½ miles, subterraneous. The length of this canal is 28 miles; in the rise from St. Quintin to the summit-level, there are 5 locks, and in the descent to Cambray, 17. The cost is stated at 12,000,000 francs, or about 2,250,000 dollars.

Canals of Great Britain. The English were a century after the French in commencing the construction of canals upon a large scale. The first considerable work of this description was the *Sankey Canal*, for which an act of parliament was passed in 1755; the object of the act being the improvement of the navigation of Sankey Brook; which plan was afterwards changed to that of a separate canal of 12 miles in length. While the work on this canal was in progress, in 1758, the Duke of Bridgewater obtained an act of parliament for making Worsley Brook navigable from Worsley Mill to the river Irwell, for the purpose of facilitating the transportation of coals from his estate to Manchester; but seeing the advantages of still-water navigation over that of a river, he conceived the project of a canal over dry land, passing the river Irwell by an aqueduct, and thus making a communication between his coal mines and the town of Manchester on one level. The plan was subsequently extended, and the duke, who lived 14 years after the commencement of the execution of his project (he died in 1772, at the age of 56), devoted his time and his fortune to the execution of this great work, with the assistance of an engineer distinguished for his genius. He diverted all his resources into this channel, and to enlarge his means for the undertaking, he limited his personal expenses to 400*l*. a year, and is even supposed to have shortened his life in consequence of the toils and anxiety attendant upon so arduous an enterprise. It was a grand project, worthy of the sacrifices he made to it. And it is a stupendous monument, whereby his memory is associated with the wealth and prosperity of our country. The works were projected by the celebrated engineer John Brindley, and executed under his direction, and constitute a lasting memorial of his genius and skill. The difficulties he had to encounter are of so interesting a nature, that we had better give a description of his labours somewhat more in detail. The principle laid down at the commencement of this business reflects much honour on the noble undertaker, as well as upon his engineer. It was resolved that the canal should be perfect in its kind, and that, in order to preserve the level of the water, it should be free from the usual obstructions of locks. But, in accomplishing this end, many difficulties occurred, which were deemed insurmountable. It was necessary that the canal should be carried over rivers, and many large and deep valleys, where it was evident that such stupendous mounds of earth must be raised, as could scarcely, it was thought, be completed by the labour of ages: and, above all, it was not known from what source so large a supply of water could be drawn, as, even upon this improved plan, would be requisite for the navigation. But Mr. Brindley, with a strength of mind peculiar to himself, and being possessed of the confidence of his great patron, who spared no expense to accomplish his favourite design, conquered all the embarrassments thrown in his way, not only from the nature of the undertaking itself, but by the passions and prejudices of interested individuals: and the admirable machines he contrived, and the methods he took, to facilitate the progress of the work, brought on such a rapid execution of it, that the world began to wonder how it could have been esteemed so difficult. Thus ready are men to find out pretences for lessening the merit of others, and for hiding, if possible, from themselves, the unpleasant idea of their own inferiority.

When the canal was completed as far as Barton, where the Irwell is navigable for large vessels, Mr. Brindley proposed to carry it over that river, by an aqueduct of 39 feet above the surface of the water. This, however, being generally considered as a wild and extravagant project, he desired, in order to justify his conduct towards his noble employer, that the opinion of another engineer might be taken; believing that he could easily convince an intelligent person of the practicability of his design. A gentleman of eminence was accordingly called in; who, being conducted to the place where it was intended that the aqueduct should be made, ridiculed the attempt; and when the height and dimensions were communicated to him, he exclaimed, "I have often heard of castles in the air, but never before was shown where any of them were to be erected." This unfavourable verdict did not deter the Duke of Bridgewater from following the opinion of his own engineer. The aqueduct was immediately begun; and it was carried on with such rapidity and success, as astonished all those who but a little before condemned it as a chimerical scheme. This work commenced in September, 1760, and the first boat sailed over it on the 17th of July, 1761. From that time, it was not uncommon to see a boat loaded with forty tons drawn over the aqueduct, with great ease, by one or two mules; while below, against the stream of the Irwell, persons had the pain of beholding ten or twelve men tugging at an equal draught; a striking instance of the superiority of a canal navigation over that of a river not in the tideway. The works were then extended to Manchester, at which place the curious machine for landing coals upon the top of the hill, gives a pleasing idea of Mr. Brindley's address in diminishing labour by mechanical contrivances.

The following are the principal canals in Great Britain:—

(Originally *denotes the first assumed cost per share, where the actual cost is not ascertained.*)

Name.	When made.	Length in miles.	Ascent & Descent, in feet and decimal parts. Total.	Pr. mile.	Breadth.	Depth.	
Aberdare, . . .	1793	$7\frac{1}{4}$	40	5.5			From Glamorganshire to Abernant. Length of the boats, 12 feet; breadth, 5. Number of shares, 221; originally, 100*l.*
Aberdeenshire,	1805	19	170	8.8	20	$3\frac{1}{2}$	From Aberdeen Harbour to Don River, at Inverary Bridge; 17 locks.
Andover, . . .	1790	$22\frac{1}{2}$	177	7.8			From Southampton Water to Andover; has been partially abandoned. Number of shares, 350; originally, 100*l.*
Ashby-de-la-Zouch.	1805	$40\frac{1}{4}$	224	5.6			From the Coventry Canal, at Marston Bridge, to an iron railway, $3\frac{1}{2}$ miles long, at Ticknall. The first 30 miles are level, forming, with the Coventry and Oxford Canal, a level of 73 miles, without including the branches. It has tunnels at Ashby-de-la-Zouch and Snareton (the length of the two is 700 yards), and an iron railway, 6 miles in length, to the Cloudshill mines. It has 2 aqueduct bridges. At Boothorpe, a steam-engine is erected, to convey the water to a feeder for the summit-level. Number of shares, 1482; cost, 113*l.*; price in 1833, 74*l.*
Ashton-under-line, or Manchester and Oldham, and branches,	1797	18	152	8.4	33 15	5	From Rochdale Canal, at Manchester, to Huddersfield, at Duckenfield; has 3 aqueduct bridges; boats of 25 tons burthen. Number of shares, 1760; average cost, 97*l.* 18*s.*; price in 1833, 120*l.*
Barnesley and branches,	1799	18	120	6.7			From river Calder, below Wakefield, to Barnby Bridge; has 1 aqueduct bridge and 20 locks. Number of shares, 720; cost, 160*l.*; price in 1833, 247*l.*
Basingstoke, .	1790	37	195	5.3			From Wye to Basingstoke; has 72 bridges and 29 locks. Number of shares, 1650; cost, 100*l.*; price in 1833, 5*l.* The Tingis branch is $5\frac{1}{2}$ miles in length. The boats are of 45 tons burthen. It has a tunnel of $\frac{3}{4}$ mile.
Birmingham, .	1772	$22\frac{1}{2}$	204	9.07	40	$4\frac{1}{2}$	Commences in the Birmingham and Staffordshire Canal, and terminates in the Birmingham and Fazeley Canal. The boats are 70 feet long and 7 wide, and of 22 tons burthen. Number of shares, 4000; originally, 17*l.* 10*s.*; price in 1833, 239*l.* The tonnage is not to exceed $1\frac{1}{2}$*d.* per mile.
Birmingham and Fazeley,	1790	$16\frac{1}{2}$	248	15	30	$4\frac{1}{2}$	From the Coventry Canal, at Whittington Brook, to Birmingham Canal, at Farmer's Bridge; has 44 locks; boats 22 tons burthen.
Brecknock and Abergavenny,	1776	33	68	2			From the Monmouthshire Canal to Brecon. There is, at Abergavenny, an iron railway a mile in length; at Wain Dew another $4\frac{3}{4}$ miles, and at Llangroiney another $1\frac{1}{4}$ mile. It has a tunnel of 220 yards, and 3 aqueduct bridges. Number of shares, 958; originally, 150*l.*; price in 1833, 80*l.*
D. of Bridgewater	1758	40	83	2	52	5	From the tide-way of the Mersey, at Runcorn Gap; and at Longford Bridge divides into 2 branches, one terminating at Manchester, the other at Pennington, near the town of Leigh. The whole lockage is the 83 feet at the Mersey, in rising from tide-water, by 10 locks. This canal, with a part of the Trent and Mersey Canal connected with it, makes a level of 70 miles, 30 of which are on this canal. Mr. Cary states that there are about 16 miles of canal under ground within the mountains at Worsley. It has 3 principal aqueduct bridges, and several smaller ones. Arched branches pass off from it at considerable distances, under the town of Manchester, from one of which coals are hoisted up to supply the inhabitants, which the proprietors, successors to the Duke of Bridgewater, are bound to furnish them at 4*d.* for 140 lbs.; an advantage to which much of the prosperity of that town has been attributed. The embankment over Stratford Meadows is 900 yards long, 17 feet high, and 112 feet wide at the base; that at Barton Bridge is 200 yards long and 40 feet high. The tonnage is 2*s.* 6*d.*

Name.	When made.	Length in miles.	Ascent & Descent, in feet and decimal parts. Total.	Pr. mile.	Breadth.	Depth.	
Bristol and Taunton,		41					From Taunton Bridge to the mouth of the Avon, below Bristol, price in 1833, 70*l*.
Burrowstonness,	1790	7					
Caistor, ...	1793	9					From Anchole to Caistor.
Caldon and Uttoxeter,		28	136	4.8			A branch of the Grand Trunk Canal, terminating at Uttoxeter.
Caledonian, . .	1822	21⅞	1905	8.6	40 bo.	20	This stupendous canal passes through a chain of lakes, or *locks*, and narrow arms of the sea; and by making 21⅞

miles of canal, and deepening the beds of the rivers Lochy and Oich, and dredging to deepen a part of Loch Nees (in the whole a distance of 4⅛ miles, making the total length of excavation 25 miles, with a lockage, up and down, of 190 feet), an interior navigation of 250 miles is opened across the central part of Scotland, from the Murray Firth, on the eastern coast, to Cantyre, on the western, and about opposite to the northern coast of Ireland; being one-half of the distance of the navigation between the same extreme points, round the northern coast by the Orkneys. It has 27 locks, including the tide-locks, one of them 170, but most, if not all, the others 180 feet long, and all 40 feet wide; thus opening a ship-navigation through the midst of the country, rising, at the summit-level, 94 feet above the tide water of the eastern coast, and 96½ feet above that of the western, showing the ocean to be 2½ feet higher on the eastern. At Fort Augustus, where it leaves Loch Ness in a north-westerly direction, this canal is cut through the glacis of the fortification, thus adding to the military defences as well as to the appearance of the fort, which, with the five locks of masonry rising behind, presents a grand combination of civil and military engineering amid romantic mountain scenery. From Loch Ness, passing in the westwardly direction of the canal to Loch Oich, 1¾ mile, the land is 20 feet above the water line, which, with the depth of water in the canal, makes an excavation, in this distance, of 40 feet in depth, with a bottom of 40 feet in breadth. To save rock-cutting, in descending, in the westwardly direction, as before, from Loch Oich to Loch Lochy, the natural difference of the surfaces of the two lakes being 22 feet, the whole area of Loch Lochy, which is 10 miles in length and 1 in breadth, is raised 12 feet. In the last 2 miles, before the canal in its westerly direction enters Loch Eil, there is a descent of 64 feet, which is passed by 8 connected locks, each 180 feet long by 40 in breadth. These locks are founded on inverted arches, exhibiting a solid and continuous mass of masonry 500 yards in length and 20 yards wide, in which no flaw has yet been discovered. The gates are of cast-iron. This system of locks has received the fanciful appellation of *Neptune's Staircase*; and the appearance of large vessels, with their masts and rigging, descending these stupendous locks, from the hill towards Loch Eil, is most majestic and imposing, exhibiting a striking instance of the triumph of art. In the distance of 8 miles, from Loch Lochy to tide-water in Loch Eil, the canal, in passing along the north-westerly bank of the river Lochy, crosses, by aqueduct bridges, 3 large streams and 23 smaller ones. Since the construction of this canal, upwards of a million of forest trees have been planted along its borders. The cost of this great national work was, for

	£.		£
Management and travelling expenses, .	29,000	Purchase and damage of land, . . .	47,900
Timber, ...	68,600	Horse labour, ...	3,000
Machinery, cast-iron work, &c., . .	121,400	Road-making, ...	4,000
Quarries and masonry, ...	195,800	Incidental expenses, ...	2,000
Shipping, ...	11,000		905,300
Labour and workmanship, ...	418,000	Add, to complete the dredging, . . .	7,200
Houses and buildings, ...	4,600		£ 912,500

Assuming the number of miles operated upon to be 25, the canal cost 36,500*l*. per mile. It was constructed under the direction of Thomas Telford, Esq.

Name.	When made.	Length in miles.	Total.	Pr. mile.	Breadth.	Depth.	
Cardiff, or Glamorganshire,	1775	25	600	24			From a sea-basin on the Severn, near Cardiff, to Merthyr; is connected with various railways, one of which is 26¾ miles long. Number of shares, 600; cost, 172*l*. 13*s*. 4*d*.; price in 1833, 290*l*.
Chester, ...	1775	17½	170	9.7			From the Dee, at Chester, to Nantwich, where it communicates with the Whitchurch branch of the Ellesmere Canal.
Chesterfield, . .	1776	46	380	8.2			From the Trent, at Stockwith, to Chesterfield; has 65 locks and 2 tunnels, together 2850 yards long, and 9½ feet wide. The lower part of the canal is navigable for boats of from 50 to 60 tons burthen, and the higher, being but 26 or 28 feet broad, is navigable for boats of only 20 or 22 tons burthen. These boats are 70 ft. long and 7 ft. broad. Number of shares, 1500; cost, 100*l*.; price in 1833, 176*l*.
Coventry, . . .	1790	27	96	3.6			A part of the line of canal between London and Liverpool, price in 1833, 680*l*.
Crinan, ...	1805	9	117	13			From Lake Gilp to Lake Crinan. Number of shares, 1851; cost, 50*l*.; price in 1833, 2*l*. 10*s*.

Name.	When made.	Length in miles.	Ascent & Descent, in feet and decimal parts. Total.	Pr. mile.	Breadth.	Depth.	
Cromford, . .	1794	18	80	4.4	26		From the Erewash Canal, at Langley, to Cromford. It has several tunnels, and passes the river Derwent by an aqueduct 200 yards long and 30 feet high. The arch over the channel of the river is 80 feet broad. Another aqueduct over a branch of the Derwent is 200 yards long and 50 feet high. Each aqueduct cost about 3000*l*. Number of shares, 460; cost 31*l*. 2*s*. 10*d*.
Croydon, . . .	1801	9½	150	15.8			From Grand Surry Canal to Croydon. It has 23 locks. Number of shares, 4546; originally, 100*l*.; price in 1833, 1*l*.
Dearne and Dove,	1804	9½	125	6.6			From the river Dove, between Swinton and Mexburgh to Barnesley Canal. The boats are from 50 to 60 tons burthen. It has two branches, of 3¼ and 1¾ miles in length.
Derby, ...	1794	9	78	8.6	44-24	4	From the river Trent to Derby. Number of shares, 600; cost, 110*l*.; price in 1833, 140*l*. It has a branch, the Erewash, 8½ miles in length.
Dorset and Somerset,	1803	42					From the Kennet and Avon Canal to the river Stour; has a branch 9 miles long.
Dublin and Shannon,	1776	65½					From Dublin, at the mouth of the Liffey, to the river Shannon, near the town of Moy. It passes 24 miles across a marsh, in which the absorbing nature of the soil rendered the work enormously expensive.
Lawtou branch,		21					
Miltoun branch,		7					
Bog of Allen br.,		3					
Edenderry br.,		1					
Kildare br., . . .		6					
Dudley, ...	1776	10½	35	3.3		5	From the Worcester and Birmingham Canal. It has 61 locks; 3 tunnels, one 3776 yards in length, another 623 yards, and the other 2926 yards, all 13½ feet wide; and near one of them, the Laplat tunnel, it passes 9 locks, nearly contiguous. Number of shares, 2060; originally, 100*l*.; price in 1833, 147*l*.
Stourbridge br.,		2					
Dudley br., . . .		1¼					
Edinburgh & Glasgow,		50					This canal is proposed to commence at Leith, in the Forth, and terminate in the Clyde, at Glasgow.
Ellesmere and Chester, and branches,	1804	109	755	6.9			This canal is said to be the first constructed in England for agricultural purposes, as well as trade. It has 1262 yards of tunnelling. Number of shares, 3575; cost, 133*l*.; price in 1833, 75*l*.
Erewash, . . .	1777	11¾	181	15.4			From the Trent to Cromford Canal; price in 1833, 750*l*.
Fazeley, ...	1790	11					Is a part of the Liverpool line, joining the Grand Trunk with the Coventry Canal. It is entirely level. The Fazeley and Birmingham, and the Birmingham, are continuations of this.
Forth and Clyde,	1790	35					From the tide-water, at the junction of the river Carron with the Forth, to Glasgow. It was the first considerable work of the kind undertaken in Scotland, having been commenced in 1777, and completed in 1790. It ascends, from the Forth to the summit, by 20 locks, 156 feet, in 10½ miles, and keeps this level 18 miles, to Glasgow, and, one mile beyond that city, terminates in the Monkland Canal basin. About 2¾ miles north of the port of Dundas, near Glasgow, a branch of the canal passes off 8¼ miles, crossing the Kelven by a magnificent stone aqueduct, to the tide-water at Bowling Bay, to which it descends by 19 locks, 74 feet in length, and 20 in breadth. When full, it has 8 feet of water; price in 1833, 540*l*.
Glasgow branch,		2¼					
Foss Dyke, . .		11	0	0			From the Trent, at Torksey, to the Witham. It is a level.
Glasgow and Saltcoats,	1812	33¼	168	5			
Glenkenns, . .	1802	27					From the Dee, at Kirkcudbright, to Dalry.

Name.	When made.	Length in miles.	Ascent & Descent, in feet and decimal parts. Total.	Pr mile.	Breadth.	Depth.	
Gloucester, . . Hockcrib branch,	1793	18½ 2			70	15 to 18	A channel for ship navigation, to avoid the windings of the Severn from Berkley Hill, where it leaves that river, to Gloucester, where it joins the river again. Number of shares, 1960; price in 1824, 100*l.*, and a loan of 60*l.* per share, making the investment 160*l.* per share.
Grand Junction, Paddington br., 6 other branches,	1805	93½ 13¾ 40	587	6.3	36 24	4½	A part of the line between London and Liverpool, from Brentford to the Oxford Canal at Braunston. It has 101 locks; passes the river Ouse and its valley by an embankment about half a mile in length, and 30 feet high. It has a tunnel at Blisworth, 3080 yards in length, 18 feet high, and 16½ wide; and another at Braunston, 2045 yards long, the other dimensions being the same as those of the Blisworth tunnel. Number of shares, 11,657½; originally, 100*l.*; price in 1833, 230*l.*
Grand Surrey,	1801	12					From the Thames, at Rotherhithe, to Mitcham. It is of large dimensions, being navigable by the Thames boats. The company pays to the Corporation of London, annually, 60*l.* for the junction of the canal with the Thames.
Grand Western, Tiverton branch,	1796	35 7					From the mouth of the Ex, at Topsham, to Taunton Bridge. Number of shares, 3096; cost, 79*l.*; price in 1833, 28*l.*
Grand Trunk, Its branch, . . .	1777	93 37	642	6.9			A part of the line between London and Liverpool. It has 4 tunnels, in length 3940 yards, and 9 feet wide. Number of shares, 1300½; price in 1824, 2150*l.* The tonnage is from 3*d.* to 4½*d.* per mile.
Grand Union,		23¼	130	5.5			From the Leicester and Northampton Union Canal, near Foxton, to the Grand Junction, east of Braunston Tunnel. Number of shares, 1521; cost, 100*l.*; price in 1824, 50*l.* The canal has, besides, a loan, at 5 per cent. interest, of 19,327*l.*
Grantham, . .	1799	33¾	148	4.4			From the Trent, near Holme Pierpoint, to Grantham. It has divided 8 per cent., and left a clear surplus of 3000*l.* to meet unforeseen accidents. Number of shares, 749; cost, 150*l.*; price in 1833, 195*l.* It is supplied with water wholly from reservoirs.
Haslingdon, . .	1793	13					From the Manchester, Bolton, and Bury Canal, at Bury, to the Leeds and Liverpool, at Church.
Hereford and Gloucester,	1790	36½	225	6.1			From the Severn, at Gloucester, to the Wye, at Hereford. It has 3 tunnels, of 2192, 1320 and 440, making in all 3952 yards. In consequence of the opening of this canal, the price of coals at Ledbury was reduced from 24*s.* to 6*s.* per ton. Shares, originally, 100*l.*; price in 1824, 60*l.*
Huddersfield, .	1798	19½	770	39.5			From Ramsden's Canal, at Huddersfield, to the Manchester, Ashton, and Oldham Canal, at Duckenfield Bridge near Marsden. It has a tunnel of 5280 yards in length. Number of shares, 6312; cost, 57*l.* 14*s.*; price in 1833, 25*l.*
Kennet and Avon,	1801	57	263	4.6			From the Avon, at Dole-mead, near Bath, to the Kennet and Newbury. It has an aqueduct bridge over the Avon. The boats are of 25 or 26 tons burthen. Number of shares, 25,328; cost, 35*l.* 5*s.*; price in 1833, 26*l.*
Kingston and Leominster,	1797	45¾	544	11.8			From the Severn, at Areley, to Kingston. It has two tunnels of 3850, and 1250, making 5100 yards.
Lancaster, . . .	1799	76	287	3.8		7	From Kirby Kendall to Houghton. It has tunnels at Hincaster and Chorley, 800 yards long in the whole. It passes the Loyne by a stone aqueduct, 50 feet high, on 5 arches, each of 70 feet span. It has also a road aqueduct, near Blackmill, 60 feet high. The boats are 56 feet long and 14 broad. Number of shares, 11,699½; cost, 47*l.* 6*s.* 8*d.*; price in 1833, 22*l.*
Leeds and Liverpool,	1771	130	841	6.4	42	4½	From Liverpool to Leeds. The boats navigating between Leeds and Wigan are of 42 tons burthen; those below Wigan, and on this side Leeds, of 30 tons. The tunnels at Foulbridge and Finnloy are, in the whole, 1609 yards long. It has a beautiful aqueduct bridge over the Ayre. The locks are 70 feet long and 15½ wide. The number of shares is 2897¾; originally, 100*l.* each; price in 1833, 455*l.* Tonnage on merchandise, 1½*d.* per mile; on coals and lime, 1*d.*; on stone, ½*d.*

Name.	When made.	Length in miles.	Ascent & Descent, in feet and decimal parts. Total.	Pr. mile.	Breadth.	Depth.	
Leicester, . . .		21½	230	10.7			From the Loughborough basin to the Soar, which has been rendered navigable as far as Leicester. Number of shares, 545; cost, 140*l.*; price in 1833, 190*l.*
Leicestershire and Northamptonshire Union,	1805	43¾	407	9.3			From Leicester to Market Harborough. It has 4 tunnels, 1056, 990, 880, and 286, in the whole 3212 yards in length. Number of shares, 1895; cost, 83*l.* 10*s.*; price in 1833, 88*l.*
Loughborough,	1776	9½	41	4.3			From the Trent, near Sawley, to Loughborough. Number of shares, 70; cost, 142*l.* 17*s.* 8*d.*; price in 1833, 1800*l.* This canal affords a striking instance of the mutability of canal property. In 1824, we find the shares at *four thousand pounds each*, they are now reduced to less than half the money, and this reduction may be mainly ascribed to the increased facilities in coast conveyance.
MarketWeighton,	1770	11	35	3.2			
Monkland, . .		12	96	8			A continuation of the Forth and Clyde Canal.
Monmouthshire,	1796	17¾	1057	53.5			This canal is remarkable for the extent of its railways and inclined planes. Number of shares, 2409; cost, 100*l.*; price in 1833, 194*l.* It has, besides, a loan of 43,526*l.* at an interest of 5 per cent.
Montgomeryshire,	1797	27	225	8.3			From a branch of the Ellesmere Canal to Newtown. Number of shares, 700; originally, 100*l.*; price in 1833, 85*l.*
Welshpool br., .		3¼					
Neath, ...	1798	14					From the river Neath, at the Giant's Grave, to the Aberdare Canal, at Abernant. It serves for the transportation of copper and lead ore from Cornwall to Glamorganshire. Number of shares, 247; cost, 107*l.* 10*s.*; price in 1833, 285*l.*
North Wilts, .	1798	8½					From the Thames and Severn Canal to the Wilts and Berks.
Nottingham, .	1802	15					From the Trent, at Nottingham, to the Cromford Canal, near Langley Bridge.
Oakham, . . .	1803	5 1	126	8.4			From Melton Mowbray to Oakham. Number of shares, 522; cost, 130*l.*
Oxford, ...	1790	91½	269	2.9	30-16	5	From the Coventry Canal to the river Isis at Oxford, and a part of the grand line between Liverpool and London. It has 3 aqueducts of very considerable magnitude, a tunnel at Newbold 125 yards long, and 12½ feet wide, and one at Fenny Compton 1188 yards long and 9½ feet wide. It rises from the level of the Coventry Canal, in 45½ miles, to the summit at Marston Tolls, 74 feet 1 inch, by 12 locks; and descends from the summit at Claydon, in 35 miles, to the Isis, 195½ feet, by 30 locks. It has 188 stone and brick bridges. It cost 178,648*l.* stock, besides 130,000*l.* loan, above half of which has been paid off. Number of shares, 1786; originally, 100*l.*; price in 1833, 560*l.*
Peak Forest, .	1800	21					From the Manchester, Ashton, and Oldham Canal, at Duckenfield, to the Chapel Milton basin. It has a railway 6 miles long. It passes the Mersey, by a bridge 100 feet high, of 3 arches, each of 60 feet span. Number of shares, 2400; cost, 77*l.*; price in 1833, 74*l.*
Portsmouth & Arundel,	1815	14½					From the river Arun, near Little Hampton, to the bay connected with Portsmouth Harbour. Number of shares, 2520; cost, 50*l.*
Ramsden's, . .	1774	8	56	7			From the Calder and Hebble Navigation to the Huddersfield Canal.
Regent, ...	1820	9	86	9.5			The last link, near London, of the chain connecting that city and Liverpool. It commences at Paddington, from the Grand Junction Canal, and meets the Thames at Limehouse, descending, by 12 locks, to a basin communicating with a ship lock. The locks have double chambers, which are estimated to make a saving of nearly one-half the usual quantity of water. It has two tunnels, one at Maida Hill, 370 yards long, the other under Islington, 900 yards. Number of shares, 12,294; cost, 40*l.* 10*s.*; price in 1833, 16*l.* 10*s.*

Name.	When made.	Length in miles.	Ascent & Descent, in feet and decimal parts. Total.	Pr. mile.	Breadth.	Depth.	
Ripon, ...	1767	7					From the river Ure, at Milby, to Ripon.
Rochdale, . . .	1804	31	613	19.7			From the Bridgewater Canal, in the town of Manchester, to the Calder and Hebble Navigation, at Sowerby Bridge. It has 49 locks, 8 aqueducts, a tunnel of 70 yards in length, and several reservoirs. Number of shares, 5631; cost, 85*l.*; price in 1833, 88*l.*
Royal Irish, . .		68	614	9			From Dublin, in a westward direction, to the Shannon, at Tasmonbarry, nearly parallel to the Dublin Canal, and about 10 miles distant from it. Its greatest elevation above the sea is 307 feet, to which it ascends from Dublin by 26 locks, and descends to the Shannon by 15 locks.
Sankey, ...	1760	12½	78	6.2	48	5	From the Mersey and Irwell Navigation, at Fiddler's Ferry, to Sutton Heath Mines. It has 10 locks, and also a tunnel, near St. Helen's. It was the first canal constructed in England.
Shorncliff and Rye, or Royal Military,	1809	18					From the sea, at Hythe, to the mouth of the river Rother. It is a level, having locks to keep in the water at low tide. It is large enough to receive vessels of 200 tons burthen. Each of its extremities is defended by strong batteries. It was constructed on account of Bonaparte's projected descent on England, and hence its name of Royal *Military* Canal.
Shrewsbury, .	1797	17½	155	9			From Shrewsbury to the Shropshire Canal. One half of the ascent is effected by locks, the other half by inclined planes. It has one tunnel. Number of shares, 500; originally, 125*l.*; price in 1833, 250*l.*
Shropshire, . .	1792	7½	453	60.4			From the Severn, at Coalport, to the Shrewsbury Canal, at Downington Wood. It has several inclined planes and railways, but no locks. Price in 1833, 138*l.*
Somerset Coal,	1802	8½	138	16.2			From the Kennet and Avon Canal, at Monkton Coombe, to Paulton. The boats are 72 feet long and 7 broad. It has 22 locks. Number of shares, 800; original cost, 50*l.*; price in 1833, 170*l.*
Radstock br., . .		7½	138	18.4			
Southampton & Salisbury,	1804	17½					From the Itchin, at Northam, to the Avon, at Salisbury
Stafford and Worcester,	1772	46½	394	8.4	30	5	From the river Severn, at Stourport, to the Grand Trunk Canal. It has 44 locks. Its boats are of 20 tons burthen. It has 3 tunnels. Number of shares, 700; cost, 140*l.*; price in 1833, 550*l.* Tonnage not to exceed 1½*d.* per mile.
Stainforth and Keadby,	1798	15					From the river Trent, at Keadby, to the Don, at Fishlake.
Stourbridge, .	1776	5	191	38.2	28	5	From the Stafford and Worcester Canal, at Stourton, to the Dudley Canal. It has 20 locks. Number of shares, 300; originally, 245*l.*; price in 1833, 190*l.*
Stover, ...	1792	6½	50	8			From the river Teign, at Newtown, to Bovey Tracey.
Chudleigh br., .		5½					
Stroudwater, .	1796	8	108	13.5			From the river Severn, at Framiload, to the Thames and Severn Canal, at Wallbridge. Price in 1833, 510*l.*
Swansea, . . .	1798	17½	366	20.9			From Swansea Harbour to Hen Noyadd. Like the Neath Canal, it serves to transport copper ore from Cornwall to Glamorganshire founderies. Number of shares, 533; originally, 100*l.*; price in 1833, 185*l.*
Llansamlet br., .		3					
Tavistock, . . .	1810	4½	237	52.7			From the river Tamar, at Calstock, to Tavistock. It has a tunnel at Morwellham, 460 feet below the surface. This tunnel led to the discovery of a copper mine. Its boats are 15½ feet in length, and 5 in breadth. Number of shares, 350; originally, 100*l.*
Mill Hill branch,		2					
Thames and Medway,	1800	8½					From the Thames, at Gravesend, to the river Medway; Number of shares, 2670; cost, 42*l.* 9*s.* 5*d.*; price in 1824, 26*l.* This canal has loans to a large amount.
Thames and Severn,	1789	30½	377	12.3	40-30	5	From the Stroudwater Canal to the Thames and Isis Navigation. The boats are of 70 tons burthen, being 80 feet long and 5 broad. It has a tunnel at Sapperton, 250 feet below the top of the hill of rock under which it passes. The bottom of this tunnel is an inverted arch. Price 29*l.*

R 2

Name,	When made.	Length in miles.	Ascent & Descent, in feet and decimal parts. Total.	Pr. mile.	Breadth.	Depth.	
Warwick and Birmingham,	1799	25					From the Warwick and Napton Canal, near Warwick, to the Digbeth branch of the old Birmingham Canal. It has a tunnel at Fazeley 300 yards in length. It has 32 locks.
Warwick and Napton,	1799	15					From the Warwick and Birmingham to the Oxford Canal. Number of shares, 980; originally, 100*l.*; in 1833, 216*l.*
Wey and Arun Junction,		16					From the river Wey, near Godalming, to the north branch of the Arun River Navigation. Number of shares, 905; cost, 110*l.*; price in 1833, 22*l.* 10*s.*
Wilts and Berks,	1801	52	376	7.2			From the Kennet and Avon Canal, at Semington, to the Thames and Isis Navigation. Price in 1823, 4*l.* 10*s.*
Calne branch, . .		3					
Worcester and Birmingham,	1797	29	128	4.3	42	6	From the Severn, at Diglis, below Worcester, to the Birmingham and Fazeley Canal, at Farmer's Bridge. Price 85*l.*
Wyrley and Essington,	1796	23	270	11.6	28	4½	From a detached part of the Fazeley Canal, at Huddlesford, to the Birmingham Canal at Wolverhampton. The boats are of 18 tons burthen. It has 28 locks. Price in 1833, 115*l.*
Hayhead br., . .		5½					
Lordshery br., . .		2¼					
Wyrley Bank br.,		4					
Essington br., . .		1					
Norwich and Lowestoff Navigation,	1829	50			50		The works near Yarmouth open an inland navigation in two directions; one 30 miles, by the Yare, the other 20 miles, by the Waveney, without a lock. The river Yare discharges at Yarmouth, about 30 miles below Norwich,

but the navigation is obstructed by shoals and shifting sands at its mouth. To avoid these obstructions, the river is to be made navigable for sea-borne vessels from Norwich to a place 20 miles lower down the river, called *Reedham Ferry*, where a new cut of 2½ miles is to be made across the marshes, to join the river Waveney at St. Olave's Bridge, whence the water communication proceeds by a small stream (Oulton Dyke), and two lakes (Oulton Broad and Lothing), from the latter connected with the sea by a channel 700 yards long and 40 feet wide, with a sea lock 50 feet wide in the clear, and 24 feet deep, for the purpose of admitting sea-borne vessels. Oulton Dyke, and Oulton Broad, are to be deepened. The lock constructed at the outlet of Lake Lothing makes an artificial harbour, the first that has been formed in England. This lock has folding gates pointing both landward and seaward, so as to admit of vessels passing in or out at any time of tide, and whether the water be higher on the outside or inside.

The great importance of navigable canals to a commercial country like Great Britain, will be a sufficient apology for the length of this article; which has been materially improved by corrections and emendations, obligingly furnished by Mr. Woulf, the celebrated canal agent, but our space will only permit a brief notice of American canals,—what more may be found necessary will have a place under INLAND NAVIGATION.

It appears, from the following outline, that not less than 2500 miles of canal are constructed, or in the progress of execution in the United States, and will probably soon be completed, making a liberal allowance for a suspension of some of the works projected and commenced. The extent of canal in the United States will soon equal that in Great Britain. The canals constructed and now in progress in the state of Pennsylvania have been estimated at a length of 900 miles; very nearly equal to that of the canals of France, but doubtless inferior in the style and durability of execution. The *Welland Canal*, in Canada, is intended for opening a sloop navigation between lakes Erie and Ontario.

The *Middlesex Canal* opens a boat navigation between Boston and the Merrimack river, and runs 28 or 29 miles, in a north-westerly direction, from its outlet into the harbour of Boston, in the town of Charlestown. The *Blackstone Canal* is constructed along Blackstone River from Providence, in Rhode Island, north-westerly 45 miles, to Worcester, in Massachusetts. The *Farmington Canal* leaves the coast of Long Island Sound at New Haven, in Connecticut, and takes a north-easterly course, towards Northampton in Massachusetts, 65 miles distant, where it is to communicate with Connecticut River. A great part of it is finished and in operation, but a portion, towards the north-eastern termination, remains to be constructed.

The *Hudson and Erie Canal* passes from Albany, in the state of New York, along the western bank of Hudson River, until it meets the Mohawk; then runs, in a north-westerly direction, up the south-western bank of that river, to the town of Rome, where it turns more westerly, on a summit-level of about 60 miles, without a lock, and passing in a line corresponding in some measure to the direction of the southern shore of Lake Ontario, and crossing the Seneca and Genesee rivers in its course, communicates with Lake Erie at Buffalo, 363 miles from Albany. This canal is connected with Lake Champlain by the *Champlain Canal*, 63 miles in length; with Lake Ontario by the *Oswego Canal*, about 38 miles long; and with Seneca Lake by the *Seneca Canal*, about 20 miles long. The *Hudson and Delaware Canal* begins at the west bank of Hudson River, near Kingston, in New York, about 85 or 90 miles north of the city of New York, and runs in a south-westerly direction 65 miles, to the Delaware River, near to the north-east corner of Pennsylvania, and the north-west of New Jersey. It then takes a general direction a little to the north-west, and keeps

the northern bank of the Delaware River for 25 or 30 miles, to the entrance of Lackawaxen Creek, from the opposite side; crosses the Delaware at a point about 110 miles north of Philadelphia, and leaving that river, keeps the northern bank of Lackawaxen Creek; then crosses it, in a westerly direction, to Riscis Gap, a distance, added to the former, of between 40 and 50 miles, as nearly as can be estimated from Mr. Tanner's map of Pennsylvania, of 1829. This canal opens the Lackawaxen coal district to Hudson River.

The *Morris Canal*, now in progress, commences at its western extremity, at the river Delaware, near Easton, and passes across the state of New Jersey in a north-easterly, then in an easterly, then in a southerly direction, 86 miles, to Newark, in that state. Its western extremity is at the eastern termination of the Lehigh Navigation in Pennsylvania, and it is intended for the transportation of Lehigh coal to New York. The *Ohio State Canal* commences at the mouth of Sciota River, where it discharges into the river Ohio, and takes a northerly course, for about 306 miles, to Lake Erie, at the mouth of the Cuyahoga river, in the town of Cleveland. This work is in rapid progress.

The *Miami Canal* is also a line of communication between the river Ohio, which it leaves at Cincinnati, and Lake Erie. Its northerly termination is in the Maumee, which discharges into the westerly part of Lake Erie. The proposed length of this canal is 265 miles. It is now in progress. *Illinois and Michigan Canal*. An act was passed in the Legislature of Illinois, Jan. 22, 1829, authorizing commissioners, "as soon thereafter as they could command funds, and might deem it expedient to commence the work, to effect a navigable communication between Lake Michigan and the Illinois River." This is the fourth projected work for making a communication between the great northern and western waters; one of the others being projected by Pennsylvania, from Pittsburgh to Erie, of which a very small part is executed; the other two are undertaken by Ohio, and both in progress. The *Lehigh Canal* commences at the Maunch Chunk Coal Mine, on the river Lehigh, and runs to Easton, on the Delaware; the whole distance of this navigation being 46¾ miles; but a part of it is river navigation, the length of the canal being 37 miles. Its eastern termination at Easton meets the western termination of the Morris Canal in New Jersey. The *Delaware Canal* commences, at its northern extremity, at Easton, about 55 miles in a right line nearly north from Philadelphia, on the north-western bank of Delaware River, the general course of which, for about 50 miles from this place, is south-easterly, when it turns, in nearly a south-westerly direction, about 30 miles, to Philadelphia. This canal, which is still in progress, is to follow the general course of the Delaware, keeping its westerly bank to Morrisville, where it bears off from the river, to avoid a bend, and proceeds, in a pretty direct course, a little to the west of south, to Bristol, on the westerly bank of the Delaware, 19½ miles N.E. from Philadelphia. The *Schuylkill Canal* is constructed on the banks of Schuylkill River, from Philadelphia, about 110 miles, to Mount Carbon, the region of the Anthracite, in Schuylkill County, the general direction being nearly north-west.

The *Union Canal* is to the westward of the town of Reading, in Berks County, Pennsylvania, about 60 miles from Philadelphia, the Union Canal branches off from the Schuylkill Canal in a general south-westerly direction, first passing up a branch of the Schuylkill, and then down the valley of the Swatara, somewhat circuitously, about 80 miles, to Middletown, a little above the junction of the Swatara with the Susquehanna. *Pennsylvania Canal* commences at Middletown, at the termination of the Union Canal, whence it is proposed to proceed up along the Susquehanna, in a westerly direction, to the Alleghanies, which are to be passed by a rail-road, now in progress, about 50 miles in length, into the valley of the Ohio, where the canal again commences, and is continued to Pittsburg, a distance in the whole, of 320 miles of canal and rail-road; the part of the canal beyond the Alleghanies being already completed, and the part on the eastern side being in progress. The *Little Schuylkill Canal* is 27 miles in length, from the mouth of the Little Schuylkill River to the coal mines. *Conestoga Canal* passes from Lancaster, in Pennsylvania, about 62 miles directly west from Philadelphia, down the Conestoga Creek, 18 miles, in nearly a south-west direction, to Susquehanna River. The *Chesapeake and Delaware Canal*, 18 miles in length, from the Delaware River to Elk River, which discharges into Chesapeake Bay, is of sufficient dimensions for the passage of coasting vessels, in the route between Philadelphia and Baltimore. *Dismal Swamp Canal* is a channel of sloop navigation, between 6 feet deep and 70 wide, along the low land between Chesapeake Bay and Albemarle Sound, and thence to Pimlico Sound. Several branches have been constructed, and the whole is in operation, being a very important work, and somewhat similar to that of the Chesapeake and Delaware Canal.

The *Chesapeake and Ohio Canal* is a gigantic enterprise, in progress, for opening a navigation of 360 miles, from Washington, along the Potomac and its branches, across the Alleghany mountains, and thence down the valley of the Youghiogeny and Monongahela rivers, to Pittsburgh, on the Ohio. The execution of this work was commenced in 1828, at the eastern extremity.

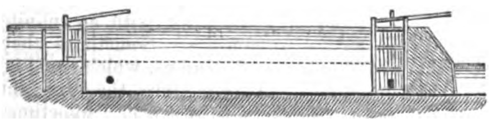
The *Louisville Canal*, though only 3 or 4 miles in length, is a work of great importance as well as great expense. It is now in progress, and is intended to form a passage along the side of the rapids of the Ohio, near to Louisville, in Kentucky. The canal is constructing of sufficiently large dimensions to admit of the passage of steam-boats; and the difficulty and expense, as in the case of the canal at Trolhatta Falls, in Sweden, is occasioned by the necessity of excavating rock. The *James and Kanhawa Canal* is a name given to works intended to form a line of transportation, partly by water and partly by land, from the Atlantic coast to the Ohio; being a navigation along James River to the Blue Ridge, partly by an artificial channel, but mostly by the river, and across the Ridge, by a well-constructed road, graduated to an inclination not exceeding 3 degrees, which has been completed, and descending, by river or canal navigation, along the Kanhawa River to the Ohio. A canal was commenced along the bank of James River, to pass the falls at Richmond, before the revolution. The work was resumed, and completed, after the establishment of the present government, by a private company; but the state has since assumed these works, and greatly enlarged them, upon an improved construction, in

the execution of the plan of the extended line of transportation above described. In Mr. Boye's map of Virginia, the canal is laid down along the north-western bank of the James River, from Richmond to Venture Falls; a distance of about 20 miles, and, by the course of the canal, probably as much as 24 or 25. The *Appomattox Canal* is about 5 miles of canal, in detached portions, being a part of a system of improvement of the Appomattox Navigation in Virginia. The *Roanoke Canal* is a similar work on Roanoke River. The *Santee Canal* is a proposed and partly executed line of navigation from Charleston to Columbia, and thence to Cambridge, in South Carolina. The whole distance is 160 miles. A canal has been cut, and for many years in operation, 22 miles in length, across from Cooper's River, which discharges into the ocean at Charleston, to Santee River. Thence the route of this navigation is proposed to pass along Santee, Broad, and Saluda rivers; the project being an improvement of the river navigation, by removing obstructions, deepening the water in shallow places, and locking round falls. The work has not hitherto been prosecuted with great success. The *Prideaux Canal*, which is a work of great magnitude, and nearly completed, will be described under INLAND NAVIGATION.

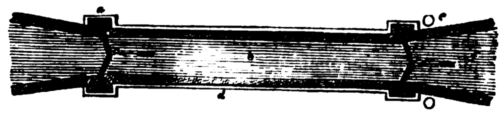
In the preceding account of canals we have studiously avoided every thing connected with the practice of canal digging, and the erection of those stupendous contrivances for facilitating the elevation and depression of vessels in their transit over irregular ground. The canal locks, or water-tight boxes, used for this purpose, hold many thousand gallons of water, and one immense series on the Caledonian Canal have not unappropriately been called the "Giant's Steps."

The Chinese drag their vessels up an inclined plane from a lower to a higher level, which requires powerful machinery, and causes considerable injury to the vessel. Now, if we contrast this primeval process with the arrangement at present pursued, the advantage will be at once apparent. One man, without the aid of machinery of any kind, will raise a barge of fifty tons burthen in a few minutes; and there are few sights better worth witnessing in the neighbourhood of our metropolis than the gratuitous one which is continually presenting itself on the great City Canal.

To render the theory of the canal-lock and its use intelligible to our readers, we must have recourse to a graphic illustration.



The above section of a canal-lock contains the pit, or central chamber, and the gates. The upper level of the canal is shown to the left of the figure, and the lower at the opposite end. Now, if we suppose the two gates connected with the lowest end to be opened, and the barge floated into the chamber, the gates are then closed, and a small channel or underground trap communicating with the higher level opened. The water will immediately enter the chamber, and raise the vessel till it is on the same level with the upper canal; the gates are then thrown open, and the barge floated out. If the object be to lower a barge, a process the reverse of the preceding is pursued. We may suppose the lock filled with water, and the barge in the chamber; the gates are then closed, and an underground passage opened communicating with the lower level; and the water is then let out and the barge sinks; so that on opening the lower gates, the barge can be passed to its destination.



A plan of the canal-lock may render this still clearer: *a* represents the posterns to which the lock gates, *c*, are attached. The walls, *d*, of the lock-pit, *b*, are usually formed of a strong timber or iron frame filled with brick-work. The higher level of the canal, *f*, communicates with the lock-pit by the tunnels *e*, and if there were no gates, the stream would pass in the direction of the arrows.

We must now point out an improvement on the preceding arrangement, adopted on the best canals, but which is attended with nearly double the expense. In the common arrangement, one lock of water is lost each time a vessel is passed, but in the double-lock this is reduced one-half, for the water in the first lock passes to the second, so that while one barge is ascending, another may be lowered, and *vice versa*. To effect this, it is only necessary to open a communication between the two locks, instead of allowing the water to escape from the higher to the lower level each time the double transfer takes place.

CANALIS ARTERIOSUS, in *Anatomy;* the vessel which joins the trunks of the pulmonary artery and the aorta in the foetus.

CANALIS MEDIUS; the canal of communication between the third and fourth ventricles of the brain. Canalis nasalis, the tube which conveys the tears from the lacrymal bag into the nose.

CANCER (the *Crab*), in *Astronomy;* one of the twelve signs of the zodiac, and one of the 48 old constellations ordinarily represented on the globe in form of a crab, and in astronomical books denoted by a figure much resembling that of the number sixty-nine, thus ♋. The reason generally assigned for its name, as well as figure, is a supposed resemblance which the sun's motion in this sign bears to that of the crab-fish. As the latter walks backwards, so the former in this part of his course begins to go backwards, or recede from us; though the disposition of stars in this sign is by others supposed to have given the first hint to the representation of a crab. The Greeks pretend, that when Herculus was contending with the Lernæan hydra, a crab which crawled upon the marsh seized his foot. The hero, however, crushed the reptile to pieces under his heel; but Juno, in gratitude for the offered service, though inconsiderable, advanced the creature to the heavens. Ptolemy makes 13 stars in the sign Cancer; Tycho, 15; Bayen and Hevelius, 29. Mr. Flamstead no less than 83. For an estimate of the comparative brightness of several stars in the constellation Cancer by Dr. Herschel, see *Phil. Trans.* vol. lxxxvii. p. 311, &c. Cancer, *tropic of*, a lesser circle of the sphere parallel to the equator; and passing through the beginning of the sign Cancer. See TROPICS.

CANCER. In medicine, this name is given to a

roundish, unequal, hard, and livid tumour, generally seated in the glandular texture. Though this is the texture in which it is believed always to originate, it may extend to others. This is doubted by some; and the disease which is often met with in the immediate neighbourhood of advanced cancer, and in different textures, is by them ascribed to mechanical pressure of the cancerous tumours, aided by the acrid discharges which accompany its ulceration. The name was derived from a supposed resemblance of the tumour to a crab, and furnishes a good example of the nomenclature from resemblance, which was very much in use in the early periods of the sciences. Two forms of cancer are recognised by physicians. They may rather be called two states or two stages of the same disease. One of these, and the first, is carcinoma, scirrhus, or concealed cancer, of some writers. The second is the open, or ulcerated cancer—ulcerated carcinoma, as it is designated by writers. Under proper internal treatment, the second stage may be kept off for some time; and, in favourable cases, the extirpation of the tumour by the knife may effect a cure. The disease is kept in check, in the first case, but is not removed, and is very prone to pass into the ulcerative stage. The fact that this can be deferred, by proper treatment, is an important one. The sufferings of the patient are thus made less, especially during the first stage; and even in the last their severity is much mitigated.

One very early symptom of carcinoma is pain. This pain differs from that which ordinarily accompanies local diseases of a different kind. It is described as *lancinating*, occurring somewhat in paroxysms, and resembling the suffering which the sudden passage of a sharp and pointed instrument would produce in the part. Besides this, there is always more or less dull pain present. The progress of the disease, and the occurrence of the second stage, are marked by increased pain of both kinds; by increase in the size of the tumour, augmented heat, greater inequality in the surface, a darker colour, and increased tenderness on pressure. When ulceration is just established, and even a little before, the patient complains of general irritation of the skin; the stomach is disturbed; and symptoms of constitutional irritation, more strongly marked, make their appearance. Ulceration begins on the *surface* of the tumour, and parts are destroyed, in succession, from without, until the whole texture presents a mass of disease. Instead of this destructive ulceration, we have, in many cases, fungous masses projecting from the diseased surface; and these at times attain considerable size. But it is not a character of carcinoma to grow, and become as large as other diseases of some of the organs in which it appears. This is especially true of it when seated in the womb. An offensive, sanious discharge proceeds from the ulcer. Bleeding often takes place from it, especially when fungous, either from mechanical irritation, though slight, or from accidental excitement of the arterial system only.

Carcinoma is a malignant disease. Its tendency is to death. The constitution has not power to overcome it; and hence, when left to itself, it is certainly mortal. Internal remedies do little more than palliate symptoms, or prevent the rapid progress to ulceration, which belongs to the disease. The only remedy is the knife; and, in cases in which the constitution and neighbouring parts are not contaminated, extirpation by the knife has removed the disease entirely. There are parts of the body which are liable to carcinoma, in which extirpation cannot be practised, and some in which, though an operation has been performed, death has nevertheless followed. In cases of this sort, especially those of the first class, palliatives only can be resorted to.

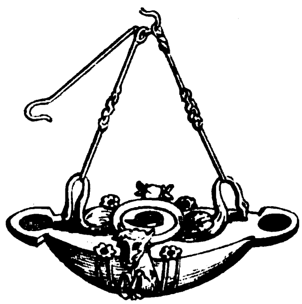
CANDEROS, in the *Materia Medica*, the name of an East Indian gum, not much known among us, though sometimes imported. It has much the appearance of common amber, only that it wants its yellow colour, being white and pellucid; we sometimes see it turned into toys of various kinds, which are very light and of a good polish. Garcias and some other authors tell us, that Borneo, and some other places where camphor is produced, have the art of adulterating the crude camphor, which they send over to us, with large quantities of this gum.

CANDELABRA. The ancients classed under this name a large family of domestic utensils intended for the purpose of holding lights. The "everlasting lights," for sepulchral purposes, as well as those for the use of the heathen altars, were generally of bronze or earthenware, and fed at stated periods by some concealed contrivance. The accompanying figure represents a Roman lamp of bronze, intended to contain a single wick, and we could select no better mode of contrasting the appliances of modern comfort compared with the so-much boasted refinements of antiquity,

than by selecting a simple Argand lamp of the present day, and observing the relative amount of light furnished by it, and the elegant Roman hand-lamp shown in our figure. The first would produce a clear and pure flame, whilst the other would only supply a murky light, poisonous to the atmosphere, and destructive to the furniture of the apartment.

Torches and lamps were the means used by the ancients for obtaining artificial light. The latter were either suspended from the ceilings of their rooms, with chains, or placed upon small moveable tables. The candelabra were originally made of cane, with one plate fixed above and another underneath, or with feet for supporters. The Grecian artists produced, in ornamenting these lamp-stands, the richest forms, which always, however, had reference to the original cane, and were encircled with an infinite variety of beautiful ornaments. Sometimes they were shafts in the shapes of columns, which could be shortened or drawn out; sometimes the luxuriant acanthus, with its leaves turned over; sometimes they represented trunks of trees entwined with ivy and flowers, and terminated by vases or bell-flowers at the top, for the reception of the lamps. Examples of these forms may be found in the British Museum and the Louvre, but particularly at the Vatican, where a gallery is filled with marble candelabra. Candelabra of yet more delicate forms, of bronze, inlaid with silver and other metals, have been found in Herculaneum. In ancient times, Tarentum and Ægina were famous for their elegant candelabra. The graceful and expressive form of this utensil was made use of for colossal works of art, particularly on

account of its resemblance to the holy torches employed in the worship of Æsculapius. The largest and grandest of those monuments was the Pharos, at the harbour of Alexandria. In modern times, this ancient form has been used for an ingenious Christian monument. At the place where the first church in Thuringia was founded by Boniface, the apostle of the Germans, only a few relics remaining of the building, which had served for more than ten centuries as a Christian temple, a candelabrum, 30 feet high, formed of sand-stone, was erected (September 1, 1811), as a symbol of the light which spread from this spot.

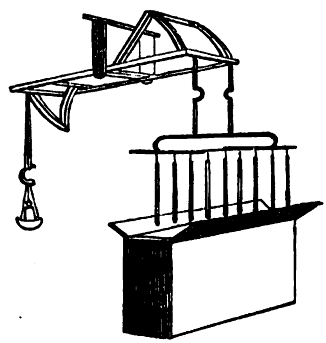


The more beautiful of the ancient candelabra were suspended by chains, and of this form we furnish an example. The Roman candelabra were invariably cast, and as such they were of necessity heavy and cumbrous, but in the present day the same symmetrical effect is produced by "striking-up" of the metal, and the beautiful bronze of antiquity imparted by an acid in a few hours.

While we now write, it is stated in the *London Journal of Science*, that two patents have been taken out in America, for the ornamenting of candelabra by making a thin skeleton of wire, and immersing it in a solution of alum, coloured by metallic oxides. This is, no doubt, a very cheap and beautiful process; the plan has for some time been adopted in the manufacture of ladies' work baskets.

Candle; a combustion of cotton and rush wicks, with various inflammable bodies for producing artificial light. Candles are either formed in moulds or dipped in fluid tallow. In the first case, a series of metal tubes are placed in a frame, and cotton wicks fixed in the centre of each tube. The tallow then descends the tubes, and the "moulds," as they are called, withdrawn as soon as cold.

The other species of candles are called "dips," and the process of dipping candles, by which a determined weight is given to any number, is of comparatively modern invention. We believe that the present Mr. Maudslay laid the foundation of a large fortune by first introducing a weighing machine for the purpose.



It is represented in the figure, and consists of a beam with two quadrants, round which the bands coil at either extremity. One of the bands is provided with a scale-pan, and to the other end of the beam is attached a frame for supporting the candle cottons to be covered with tallow. Now if we suppose the tallow to be raised to the required temperature by a fire at the bottom of the oblong copper cistern, and the cottons immersed, the precise amount of tallow adhering to the wick is shown by the increase of weight necessary to balance it in the scale-pan. When the tallow is cold, the dipping may be repeated till the candles have acquired the proper size.

A patent for an improved mode of manufacturing candles has been lately taken out by Dr. Bulkley, His improvements in making candles consist in two particulars:—first, in making wax candles in moulds instead of forming them by rolling the wax, which is the ordinary way of producing wax candles; and secondly, in making a case of wax shaped like a candle, which is to be afterwards filled with tallow or oil, or other combustible material suitable for making candles.

The first object requires but little farther explanation. To cast wax candle in moulds, it is obvious, that the wax must must be poured into the moulds in a hot and liquid state, and when perfectly cold, the end of the candle is to be struck with a small wooden mallet for the purpose of disengaging it from adhesion to the surface of the mould, when it may be withdrawn.

In putting the second feature of the invention into operation, it is proposed to pour into the candle-moulds the melted wax, as in the previously described process of moulding; and on the wax having cooled and become partially set or hardened, which it will do round the internal surfaces of the moulds before the wax in the central part of the candle has become set, then pour out of the mould the liquid portion of the wax which filled the central part of the candle, and allow the shell of wax thus formed on the surface of the mould to become hard. This shell may then be made the mould in which melted tallow is afterwards poured. There is a third principle spoken of by the patentee, but it is of less importance than those already enumerated.

There is another patent improvement which should be noticed. The main feature of it consists in the use of two small wicks instead of one, and in banding the cotton round with a small metallic spiral of wire. The smallness of the cotton ensures a more perfect combustion than could otherwise be obtained, while the band of wire obviates the necessity for snuffing. We can hardly conceive any thing more simple or efficacious.

Previous to the year 1831, candles had been subject to an excise duty, their consumption therefore could be pretty accurately ascertained. During the year 1829, the total weight of wax, spermaceti, and tallow candles consumed, amounted to 116,206,543 pounds, the net revenue derived from which amounted to 489,059*l.* 1*s.* 9*d.*

To ascertain the illuminating power of different sorts of candles, first weigh one of each sort to be tried; light them all at the same instant; and after the lapse of any given time, say half an hour, extinguish and again weigh them: compare how much each has lost in weight; that which has lost most, is the sort which affords the strongest light.

In order farther to know the comparative expense of burning candles of different kinds, and of various sizes, the reader may consult the following table, which presents the average result of a series of ex-

periments madè with a view to the determination of this point :—

Description of wick.	Number of candles to the pound.	Weight of one candle. oz.	Weight of one candle. dr.	Length of time one candle will burn. H.	Length of time one candle will burn. M.	Time that a pound will last. H.	Time that a pound will last. M.	Expense of burning candles of each description, taking as a suppositive price 10s. per doz. in farthings and 100th parts, whence may easily be deduced the proportional expense, when they are at any other price.
Small wick	18	—	14	3	15	59	25	8.078
Small wick	18	—	13½	2	40	50	33	9.475
Large wick	16	—	15½	2	40	44	—	10.909

	4	4	—	9	3	36	12	15.911
	3½	5	2¾	17	30	54	4	10.654

It is curious to mark the number of hours, during which we must of necessity have recourse to artificial light; and we give the substance of some observations made by Mr. Bevan, which accurately defines the limits of day and night for the most interesting months of the year, when the spring is rising beautiful out of the dark grave of winter.

Day.	JANUARY. End, Morning.	Begin, Evening.	Day.	End, Morning.	Begin, Evening.

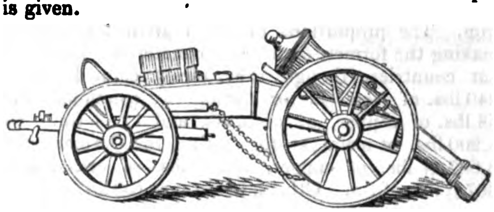
Candil, in *Commerce;* an East Indian weight, equal to 540 pounds avoirdupois.

Canella Alba; the inner bark of the *canella alba*, a tree growing in the West Indies. It is brought to this country packed in casks and cases, in long pieces, some rolled in quills and others flat; the quilled sort is considerably thicker than cinnammon, and the flat nearly a quarter of an inch in thickness. The quilled pieces are yellow on both sides; the flat pieces are yellow on the outside, and pale brown within. The odour of both kinds when fresh broken, is aromatic, something like a mixture of cloves and cinnamon, and the taste slightly bitter, and extremely warm and pungent.

Canis Major (the *Great Dog*), in *Astronomy;* a constellation of the southern hemisphere, below Orion's feet, though somewhat to the westward of him; whose stars Ptolemy makes 29; Tycho only observed 13; Helvelius 51; in the Britannic Catalogue they are 31.

Canis Minor (the *Little Dog*); a constellation of the northern hemisphere. In Ptolemy's Catalogue there are 2 stars; in Tycho's 5; in Hevelius's 13; and in the Britannic Catalogue 14.

Cannon; a heavy metallic gun, which is moved by the strength of men and horses. It is mounted on a carriage, and iron (formerly stone or lead) balls are projected to a distance from it by the force of gunpowder. The interior of the cannon is called the *bore*. The solid piece of metal behind is named the *breech*, and terminates in the *button*. The *dolphins* (so called because they used to be made in the form of this animal) are the handles by which the piece is mounted or dismounted. The aperture through which the fire is introduced into the bore, to ignite the charge, is called the *vent* or *touch-hole*, in which a small tube, used to contain the priming, is placed previous to firing. The supports, which are denominated *carriages*, are mounted on trucks, as in the case of ship-guns or garrison-guns, or on two wheels, as in the case of field-pieces, of which an example is given.

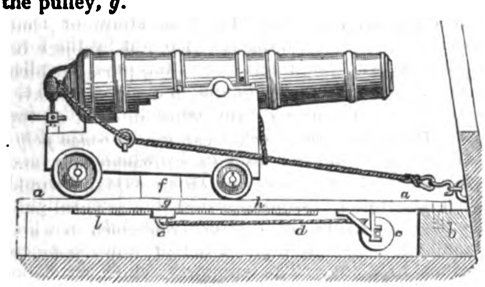


When a field-piece is to be moved, a two-wheeled frame is fixed to the carriage, which is called a *limber*, and this process is called to *limber up*. The charge, or cartridge, is a bag filled with powder, carried near the cannon. The cannon is fired by means of the *match*, which is a lighted bunch of tow, wound round a small stick; or by a tube, filled with the priming-powder, from which a piece is broken off every time, and forced into a stick, to light the charge. On board most of the English ships there are cannon fired by means of locks. To perform the labour required in managing cannon, is called to *serve the guns*.

Cannon were formerly dignified with great names. 12 cast by Louis XII. were called after the 12 peers of France. Charles V. had 12, which he called the *Twelve Apostles*. One at Bois le Duc is called the *Devil;* a 60-pounder, at Dover Castle, is named *Queen*

Elizabeth's Pocket-pistol; an 80-pounder, at Berlin, is called the *Thunderer*; another at Malaga, the *Terrible*; two 60-pounders at Bremen, the *Messengers of Bad News*. In the beginning of the 15th century, names of this sort were abolished, and the following came into general use:—cannon royal, or carthoun, carrying 48 pounds; bastard cannon, or $\frac{3}{4}$ carthoun, 36; half-carthoun, 24; whole culverins, 18; demi-culverins, 9; falcon, 6; saker. lowest sort, 5; ordinary, 6; largest sort, 8; basilisk, 48; serpentine, 4; aspick, 2; dragon, 6; siren, 60; falconet, 3, 2 and 1; moyens, which carried a ball of 10 or 12 ounces: rabinets carried one of 16 ounces. Cannons are at present named from the weight of the balls which they carry, *6-pounders*, *12-pounders*, &c. The length of the cannon is in proportion to the *calibre*.

A ship cannon of the best kind is shown in the figure beneath. The line of timber on the right of the engraving represents the bulwark of the vessel. The cannon being supported by the carriage, *f*, traverses on the plane *a a*, and when it has by its recoil been thrown back sufficiently for loading, it may afterwards be drawn up to the port-hole by a single individual applying his power at the wheel and axle, *c*. The rope, *d*, by which this is effected passes round the pulley, *g*.



Brass cannons, or cannons made of mixed metal, are said not to be so well calculated for hard service, or quick and continued firing, as those made of iron. The proportions of the ingredients used in making the former, do not differ materially in different countries, though they rarely coincide. To 240 lbs. of metal fit for casting, we commonly put 68 lbs. of copper, 52 of brass, and 12 of tin. To 4,200 lbs. of metal fit for casting, the Germans put 3,687 $\frac{4}{11}$ lbs. of copper, 204 $\frac{10}{11}$ lbs. of brass, and 307 $\frac{8}{11}$ lbs. of tin. Others, again, use 100 lbs. of copper, 6 lbs. of brass, and 9 lbs. of tin; and others 100 lbs. of copper, 10 lbs. of brass, and 15 lbs. of tin.

It seems to be the general opinion that cannon were first made use of in 1336 or 1338; but Don Antonio de Capmany has produced some statements, which render it almost certain that some sort of artillery was used by the Moors in Spain, so early as 1312. Cannons were certainly used by the English in 1347, at the siege of Calais, and by the Venetians at Chiaggia in 1366, and in their wars with the Genoese in 1379 and 1380. The Turks employed them at the sieges of Constantinople, in 1394 and 1453. When first introduced, they were for the most part very heavy and unwieldy, and threw balls of an enormous size: they were, however, owing to their frequently bursting, about as dangerous to those using them as to their opponents.

Cannon took their name from the French word *canne* (a reed). Before their invention, machines were used for projecting missiles by mechanical force. These were imitated from the Arabs, and called *ingenia*; whence *engineer*. The first cannon were made of wood, wrapt in numerous folds of linen, and well secured by iron hoops. They were of a conical form, widest at the muzzle. Afterwards, they received a cylindrical shape. At length they were made of iron bars, firmly bound together, like casks, by iron hoops. In the second half of the 14th century, they were formed of an alloy of copper and tin, and in process of time other metals were added. Some attribute the invention of cannon to the Chinese, and say that there are now cannon in China, which were made in the 80th year of the Christian era. From the Chinese the Saracens probably learned to manufacture them, and Callinicus, a deserter from Heliopolis, in Phœnicia, made them known in 670 (676), to the Greek emperor Constantinus Pogonatus.

Bombards were brought into use in France in 1338, and according to another and more doubtful authority, Solomon, king of Hungary, used them in 1073, at the siege of Belgrade. From all these accounts, it appears that the true epoch of the invention of cannon cannot be exactly determined: it is certain, however, that they were actually in use about the middle of the 14th century. In 1370, the people of Augsburg used to cast cannon. In the beginning of the 15th century, nearly all the countries of Europe, except Russia, where cannon were first cast in 1475, were provided with them. The lead cannon which were invented and employed by the Swedes, between 1620 and 1632, in the thirty years' war, were lined with tubes of wood or copper, and secured on the outside with iron rings. The art of firing red-hot balls from cannon was invented by Major-general Weiler, of the Electorate of Brandenburg. In the commencement of the 16th century, Maurice of Switzerland discovered a method of casting cannon whole, and boring them, so as to draw out the interior in a single piece. Arms for expeditious firing, loaded from behind, and having the charge closed in with a wedge, were introduced by Daniel Spekle (who died 1589), and Uffanus. In 1740, cannons were made of ice at St. Petersburg, and balls of many pounds weight were projected without injuring the pieces.

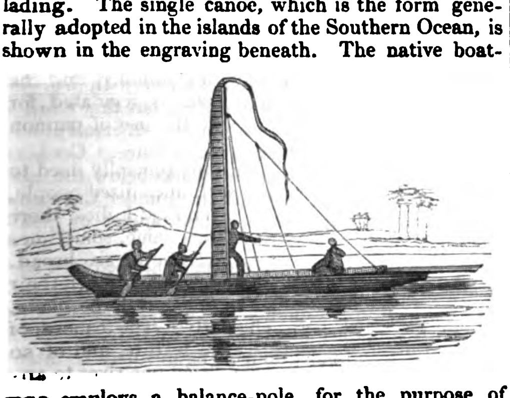
Cannon-clock is a contrivance invented by Rousseau, and placed in the garden of the *Palais Royal*, and in the Luxembourg at Paris. A burning-glass is fixed over the vent of a cannon, so that the sun's rays at the moment of its passing the meridian, are concentrated by the glass on the priming, and the piece is fired. The burning-glass is regulated for this purpose every month. (For the use of cannon in naval warfare, see SHIP.)

CANOE, also CANOA; the term generally used to designate the small vessels which uncivilized people, living near the water use. In the East I dies, there is a kind of boat which goes by this name, sometimes from forty to fifty feet long, and five or six broad. The North American Indians generally impel their canoes with paddles, which have a very large blade, and are managed perpendicularly. The canoes of Canada are of the most fragile texture, and of so little weight, that in passing from one river to another, the boatmen carry them on their heads across their portages. They are mostly covered with bark, the pieces of which are sewed together with a kind

of grass. This bark is generally not more than a quarter of an inch in thickness; yet in these frail vessels the Indians and Canadians do not hesitate to descend very dangerous rapids. The Esquimaux are exceedingly dexterous in the management of their canoes. These consist of a light wooden frame, covered with seal-skins, sewed together with sinews. The skins are not only extended round the bottom and sides, but likewise over the top, forming a complete deck, and having only one opening to admit the Indian to his seat. To this hole a flat hoop, rising about four inches, is fitted, to which is fastened the surrounding skin. The paddle is about ten feet long, light, and flat at each end. A canoe, somewhat similar to this, is found among some of the northern tribes, but which is so curious, as to deserve a particular illustration.

Seal or hippopotamus skins are sewed together, and in some cases a single skin answers the purpose of forming a large and buoyant float. When the air is expelled, the whole canoe may be placed in a very small space, and carried in the fishing-bag of the navigator.

In the Esquimaux language, the canoe is called a *kaiak*, or *man's boat*, to distinguish it from *umiak*, the *woman's boat*, which latter is a large boat for transporting the women, with their families and possessions. The Greenlanders and Esquimaux use the same kind of canoes, and it is astonishing, when we consider their insignificant construction, at what a distance from the regions they commonly inhabit, these people, especially the former, are found in them. In the islands of the South Sea, the natives have a double canoe, united by a strong platform, serving in this way as one vessel. Such a canoe is capable of carrying a number of persons, and a considerable lading. The single canoe, which is the form generally adopted in the islands of the Southern Ocean, is shown in the engraving beneath. The native boat-



man employs a balance-pole, for the purpose of equipoising the action of the wind and weight of the sail, which would otherwise overset the frail barque.

CANON, in *Music*, signified with the ancient Greeks, what now is called *monochord*. At present, it signifies a composition in which the several voices begin at fixed intervals, one after the other, and in which each successive voice sings the verse or the strain of the preceding one. In Italian, therefore, it is called *fuga di consequenza;* in Latin, *canon perpetuus*, or continuous fugue; in German, *Kreisfuge* (circulating fugue). Sometimes each voice begins with the same, sometimes with different notes. Canons may be finite or infinite. The former end, like any other compositions, with a cadence, while the infinite canon is so contrived, that the theme is begun again before the parts which follow are concluded. By this means, the performance might be continued to an indefinite length. A canon may consist of two, three, four, or more voices. Generally only one voice of a canon is written, and a sign shows the place where the other voices are to begin. Formerly, at the beginning of canons, it was the custom to place the directions by which they were to be deciphered and sung. These directions were called the *rule* or *canon*, and thence arises the title which such compositions have since retained. Canons differ from ordinary fugues; for, in the latter, it is sufficient that the subject be occasionally repeated and imitated according to the laws of counterpoint; but in the former, it is essential that the subject be strictly repeated by all the succeeding parts; which repetition may be made in the unison or octave, the fourth, or the fifth, or any other interval of the scale. There are several other canons, as *canon polymorphus*, *canon pertonos*, *canon per diminutionem*, and *canon per augmentationem*, which to explain, would exceed our limits. Sometimes, also, a musical passage of a composition, in which one voice repeats, for a short time, another, is called improperly, a *canon*.

CANOPY, in *Architecture* and *Sculpture ;* a magnificent kind of decoration, serving to cover and crown an altar, throne, tribunal, pulpit, chair, &c.

CANTABILE; a term applied to movements intended to be performed in a graceful, elegant, and melodious stile.

CANTATA; an elegant and passionate species of vocal composition, consisting of an intermixture of air and recitative. It was invented by Barbara Strozzi, a Venetian lady, who flourished about the middle of the 17th century, and was at one time extended to such length as to form a little opera, but has since been cultivated in Italy, Germany, and England, only as chamber music.

CANTEEN (from the French *cantine*, Spanish *cantina*) signifies both a bottle-case and a tavern for soldiers. In military language it denotes a little coffer divided into minute portions for holding an officer's eating utensils; likewise, a semi-cylindric tin case, carried over a soldier's knapsack, to hold his cooked victuals in; also a vessel to hold the ration of spirits or wine served out to the English troops when employed abroad.

Canteen, also signifies a public house, licensed in English barracks or forts, to sell liquors and tobacco to the soldiers.

CANT TIMBERS, in ship-building; those timbers which are situated at the two ends of a ship. They derive their name from being *canted*, or raised obliquely from the keel, in contradistinction from those the planes of which are perpendicular to it.

CANTHARIDES, or Spanish fly, in *Medicine;* the name of a kind of fly, the *cantharis vesicatoria*, Geoffray; *meloë vesicatoria*, Lin.; *lytta vesicatoria*, Fab.; belonging to the family of the *trachelides*. They are very common in Spain, Italy, and France, where they are found in large families on the ash, lilac, liburnum, &c. Their body is from 6 to 10 lines long; the feelers are black, setaceous, composed of 12 articulations; the elytra long, flexible, of a shining, golden green, and the tarses of a deep brown. Their odour is strong, penetrating, peculiar, and unpleasant; their taste extremely acrid; their powder is of a brownish gray, intermixed with shining particles of a metallic green colour. According to Robiquet, they contain, with several other ingredients, a peculiar substance called *cantharidin*. These insects are, of all the vesicating substances, those which are most commonly used. Their action is principally confined to the skin; however, their active principles may be absorbed, and cause serious accidents. The application of a blister is often followed by strangury, hæmaturia, priapism, &c. Taken internally, they act as the most energetic acrid poison; they produce irritation on the intestines, and especially affect the genito-urinary organs, which they stimulate violently. In certain disorders, they are administered in small doses as powerful stimulants. The medicine is of a very dangerous character, and its use requires the greatest caution on the part of the physician. Several species of blistering fly are found in the United States, some of which are more powerful than the Spanish fly.

CANTHARIDIN, the vesicating principle of the *cantharides*, or Spanish fly, is white, in small crystalline scales, insoluble in water and cold alcohol, from which it precipitates by cooling. The vesicating properties could be extracted from cantharides by oil of turpentine, and probably a satisfactory ointment be prepared by merely evaporating the oil of turpentine at a moderate temperature. See CANTHARIDES.

CANVASS, in *Commerce;* a coarse sort of linen or hempen cloth, usually wove open and regularly in little squares; serving for a variety of domestic purposes. Canvass also is the cloth on which painters usually draw their pictures; the canvass being smoothed over with a flat stone, then sized, and afterwards whited over, makes what the painters call their primed cloth, on which they draw their first sketches with a coal or chalk, and afterwards finish with colours.

CAOUTCHOUC. This substance which has been improperly termed elastic gum, and vulgarly, from its common application to rub out pencil marks on paper, *India rubber*, is obtained from the milky juice of different plants in hot countries. The chief of these are the *irtropha elastica*, and *urceola elastica*. The juice is applied, in successive coatings, on a mould of clay, and dried by the fire or in the sun; and when of a sufficient thickness, the mould is crushed and the pieces shaken out. Acids separate the caoutchouc from the thinner part of the juice at once by coagulating it. The juice of old plants yields nearly two-thirds of its weight; that of younger plants less. Its colour when fresh is yellowish-white, but it grows darker by exposure to the air. The elasticity of this substance is its most remarkable property; when warmed, as by immersion in hot water, slips of it may be drawn out to seven or eight times their original length, and will return to their former dimensions. Cold renders it stiff and rigid, but warmth restores its original elasticity. Exposed to the fire, it softens, swells up, and burns with a bright flame. In Cayenne it is used to give light as a candle.

CAPERS; the pickled buds of the capperis spinosa, a low shrub generally growing out of the joints of old walls, and the fissures of rocks, in most of the warm parts of Europe. Capers are imported into Great Britain from different parts of the Mediterranean; the best from Toulon, in France. Some small salt capers come from Majorca, and a few flat ones from about Lyons. The duty of 6*d*. per lb. on capers produced in 1829, 1096*l*. 2*s*. 7*d*. nett, showing that 43,845lbs. had been entered for home consumption.

CAPILLARY TUBES, in *Physics;* little pipes, the canals of which are extremely narrow, their diameter being only a half, third, or fourth, &c. of a line. If one end of a tube of this sort, open at both ends, be immersed in a fluid which adheres to glass, as water, the liquor within the tube will rise to a sensible height above the surface of that without, and the height to which it will rise is inversely as the diameter of the tube, at least unless the tubes are excessively fine. This phenomenon is explained by the attraction which exists between the glass and the fluid. Such liquids as do not adhere to glass do not rise in the tube: on the contrary, they stand lower within than without it. The phenomenon of the rise of liquids in such tubes is exhibited in numberless instances in nature, as in the rising of the sap in plants. See ATTRACTION.

CAPILLARY VESSELS; the minute vessels in which the arteries terminate, and from which, in a way not well understood, the veins commence. The distinction between the arteries and veins is, therefore, lost in these vessels. The support of the solid, and the formation of the fluid parts of the system take place especially in these vessels.

CAPITAL, in *Architecture*. See ARCHITECTURE.

CAPOC; a sort of cotton, so short and fine, that it cannot be spun. It is used in the East Indies to line palanquins, to make beds, mattresses, &c.

CAPONIER, or CAPONNIERE, in fortresses; a place which is covered against the fire of the enemy, on the sides, sometimes also above, and serves for the connection of two works, or for maintaining an important point. In particular—1. a passage secured by two parapets in the form of *glacis*, which leads through the dry ditch from one work to another; for instance, from the chief wall to the ravelin. If danger is to be apprehended only from one side, and consequently only one parapet is made, it is called a *demi-caponniere:* if it is covered above with hurdles or with wood, it is called a *coffer:* but this word is often used indifferently for *caponniere*.—2. Small blockhouses in the covered way for its defence. Coehorn laid out similar, but less useful works below the glacis, and Scharnhorst proposes them under the name of *field-caponnieres*, for the saliant angles of field-fortifications.

CAPRICCIO. *Caprice* is the name applied to a sort of musical composition, in which the composer follows the bent of his humour. The *capriccio* may be used with propriety in pieces for exercise, in which the strangest and most difficult figures may be introduced, if they are not at variance with the nature of the instrument or of the voice.

CAPRICORN (the *Goat*), in *Astronomy;* a southern constellation and the tenth sign of the zodiac, from

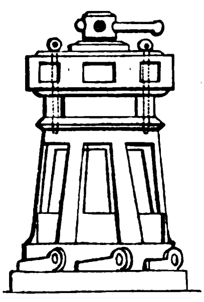
which also the tenth part of the ecliptic takes the same denomination. This was one of the 48 constellations received from the Egyptians by the Greeks. The stars in the constellation of Capricorn, in Ptolemy's and Tycho's catalogue, are 28; in that of Hevelius 29; and Mr. Flamstead, in the Britannic Catalogue, enumerates 51.

CAPSICIN. Cayenne pepper contains a peculiar substance, discovered by Forchhammer, and called *capsicin* by Dr. C. Conwell, which, according to the latter, when perfectly pure, is tasteless, inodorous, and crystallizes in acicular fragments. It is neither acid nor alkaline.

CAPSTAN, in ship building, is a mechanical power employed to facilitate labour in elevating the anchor, and for other purposes in which great force is required. It is a very extraordinary circumstance, that while improvements have been made in every other part of naval machines, but little has been effected in this, and we gladly notice a patent for the above purpose, by Mr. Hindmarsh.

The object of this improvement is to enable a capstan or windlass to be occasionally worked with increased power, which is proposed to be effected by placing toothed gear, partly in the drum-head of the capstan, and partly in the upper part of the barrel.

The drum-head, and also the barrel, turn loosely upon a central spindle, independent of each other, and are connected together either by the toothed gear, or by bolts. On raising or withdrawing the connecting pinion from the toothed wheels, and then locking the drum-head and barrel together, the capstan works with a power, only equal to that exerted by the men at the capstan bars, as an ordinary capstan; but on lowering the pinion into gear with the wheel work, and withdrawing the bolts which locked the drum-head to the barrel, the power exerted by the men becomes increased, in proportion to the diameters and numbers of teeth in the wheels and pinions.



The barrel, with the whelps, turns loosely upon a vertical spindle, fixed into the deck of the vessel. The drum-head also turns loosely upon the same spindle. The circular frame, in which the axis of the toothed wheels are mounted, is fixed to the central spindle. The rim, with internal teeth, is made fast to the top of the barrel; and the pinion which slides upon the spindle, is connected to the drum-head.

CAPUT-MORTUUM (*dead head*); a technical expression in chemistry for the deposit in the retort, arising from dry distillation; because, if the operation is continued, volatile substances cease to be given off.

CARABINE; a term for a kind of gun, which is now out of use. At present, short guns, used by the cavalry, have this name. Tacticians entertain very different opinions respecting this kind of arms. Some think that they are of no use whatever, as the aim from on horseback is extremely uncertain. In some armies, every third man of certain regiments of cavalry is armed with a carabine. The word *carabine* is found in all European languages, with different endings only. Many derive the word from *Calabria*, which, for a long time, was famous for a certain light cavalry. The transformation of the *l* into *r* would not be extraordinary. Du Fresne derives the word from a kind of arms called *chavarina*, of which mention is made in the 14th century.

CARBON. Charcoal, as we are familiar with it in common life, contains hydrogen and saline and metallic substances. Accordingly, it became necessary to introduce a peculiar term for its pure base, and the one adopted by chemists was *carbon*. This element, besides forming the inflammable matter of charcoal, exists largely in animal substances, and is extensively distributed in the mineral kingdom.

The only body in which carbon has been found to exist in a state of absolute purity, is the diamond. This precious stone has always been esteemed as the most valuable of the gems—a superiority which it owes to its hardness, lustre, and high refractive power. Diamonds are brought from India and from Brazil. Those of India, which have been the longest known, are principally found in the kingdoms of Golconda and of Visiapour. Those of Brazil, discovered at the commencement of the 17th century, belong to the district of Serro de Frio. The situations in which they occur are such as to favour the idea of their recent formation; since they exist disseminated through a loose, ferruginous sandstone, or quite detached in a sandy soil; and, in both cases, are situated at no great depth below the surface. In Brazil, the conglomerate in which they exist is called *cascalho*; from which they are extracted by washing, in the same manner as gold. The diamond uniformly occurs crystallized, and presents a great variety of forms; all of which yield readily to mechanical division parallel to all the planes of the regular octohedron, which, therefore, is the form of the primary crystal, and under which figure it is sometimes found in nature. The faces of its crystals are very frequently curved, so as to communicate to them a rounded appearance. They are commonly limpid; and are either colourless, or of a yellowish, bluish, yellowish-brown, black-brown, Prussian blue, or rose-red colour. Specific gravity, 3.5. Its hardness is extreme; so that it can be worn down only by rubbing one diamond against another, and is polished only by the finer diamond powder.

The weight, and, consequently, the value of diamonds, are estimated in carats, one of which is equal to four grains; and the price of one diamond, compared with that of another of equal colour, transparency and purity, is as the squares of the respective weights. The average price of rough diamonds, that are worth working, is about 2*l.* for the first carat. The value of a cut diamond is equal to that of a rough diamond of double weight, exclusive of the price of workmanship; and the whole cost of a wrought diamond of

1 carat	may be about 36 dollars, or		£ 8
2 carats	is	$2^2 \times £8 =$	32
3 do.	is	$3^2 \times 8 =$	72
4 do.	is	$4^2 \times 8 =$	128
100 do.	is	$100^2 \times 8 =$	80,000

This rule, however, is not extended to diamonds of more than 20 carats. The larger ones are disposed of at prices much beyond their value by that computation. The snow-white diamond is most prized by the jeweller. When transparent, and free from cracks, it is said to be of the *first water*.

The following are some of the most extraordinary diamonds known:—one in the possession of the

rajah of Mattan, in the island of Borneo, where it was found about a century ago: it is shaped like an egg, and is of the finest water: its weight is 367 carats, or 2 oz. 169 grs. Troy. Another is the celebrated Pitt diamond, now among the crown jewels of France, weighing 136 carats; another in the sceptre of the Emperor of Russia, of the size of a pigeon's egg; and another in the possession of the Great Mogul, which is said to weigh 280, and which, in a rough state, weighed 793 carats. From the fact that transparent inflammable bodies refract light in a ratio greater than their densities, Sir Isaac Newton conjectured that the diamond might consist of an unctuous matter coagulated. The Florentine academicians had rendered its combustibility probable, by exposing it to the solar rays of a powerful burning-glass, and observing that it gradually disappeared, or was consumed. Subsequent experiments settled the question, by proving that the diamond lost none of its weight when calcined out of contact with the air; but, on the contrary, that it was dissipated when heated in contact with this fluid. It still remained, however, to be discovered, what was the true nature of the diamond. This was accomplished by Lavoisier, who enclosed diamonds in jars filled with atmospheric air or oxygen gas, and, after having caused them to disappear by the heat of a burning-glass, examined the air in the vessels. He found it to exhibit precisely the same properties as the air which results from the combustion of charcoal. This experiment was also performed by Mr. Pepys, who demonstrated the nature of the diamond by another arrangement. A diamond was enclosed in a cavity made in a piece of pure, soft iron; a stopper of the same metal was driven into it, and the mass was put into a small crucible, which was covered, and this into a second; the space between them being filled with pure silicious sand. The whole was exposed, for some time, to an intense heat. When examined, the diamond had disappeared, and the iron, with which it had been in contact, was converted into steel. Now steel is a compound of iron and carbon; and, as the diamond was not visible, and as there was no source from which the carbon could have been obtained, the conclusion was unavoidable, that the diamond was pure carbon. Yet so different is this mineral from charcoal, that it was, for a time, imagined that it contained some other element than carbon; but the numerous and delicate experiments of Sir H. Davy, and several other chemists, failed of detecting any thing else in its composition; and, although there exists so great a difference between the diamond and charcoal, in their external properties, we are forced to believe that they are identically of the same nature. The diamond is, therefore, pure carbon, and differs from charcoal (leaving out of question its trifling impurities) only in the arrangement of its molecules.

The substance in which carbon exists next in purity is charcoal. For common purposes, this is prepared by piling billets of wood in a pyramidical form, with vacuities between them for the admission of air, covering them with earth, and inflaming them. In consequence of the heat, part of the combustible substance is consumed, part is volatilized, together with a portion of water, and there remains behind the ligneous fibre only of the wood, in the form of a black, brittle, and porous body. When required pure, and in small quantities, for the purposes of the chemist, it may be obtained by immersing the wood in sand contained in a crucible exposed to heat. According to the experiments of Messrs. Allen and Pepys, the weight of charcoal obtained from 100 parts of different woods was as follows:—fir, 18.17; lignum vitæ, 17.25; box, 20.25; beech, 15; oak, 17.40; mahogany, 15.75.

Lampblack is charcoal in a state of minute division, and is prepared for the demands of trade from the dregs which remain after the eliquation of pitch, or else from small pieces of fir-wood, which are burned in furnaces of a peculiar construction, the smoke of which is made to pass through a long horizontal flue, terminating in a close, boarded chamber. The roof of this chamber is made of coarse cloth, through which the current of air escapes, while the soot, or lampblack, remains behind. *Coke* is a peculiar kind of charcoal, which remains in the retort, after the heating of coal to procure the coal gas.

Ivory-black, or *animal charcoal*, is obtained from bones made red-hot in a covered crucible, and consists of charcoal mixed with the earthy matters of the bone.

Wood charcoal, well prepared, is of a deep-black colour, brittle and porous, tasteless and inodorous. It is infusible in any heat a furnace can raise; but, by the intense heat of a powerful galvanic apparatus, it is hardened, and at length is volatilized, presenting a surface with a distinct appearance of having undergone fusion. The density of charcoal, according to Mr. Leslie, is little short of that of the diamond itself, although its specific gravity has usually been considered as low as 2.00. Charcoal is insoluble in water, and is not affected by it at low temperatures; hence wooden stakes, which are to be immersed in water, are often charred to preserve them.

Owing to its peculiarly porous texture, charcoal possesses the property of absorbing a large quantity of air, or other gases, at common temperatures, and of yielding the greater part of them when heated. It appears from the researches of Saussure, that different gases are absorbed by it in different proportions. He found that charcoal prepared from box-wood absorbs, during the space of 24 or 36 hours, of

Ammoniacal gas .	90	times its volume;
Muriatic acid . .	85	do.
Carbonic acid . .	35	do.
Oxygen	9.25	do.
Hydrogen . . .	1.75	do.

Charcoal likewise absorbs the odoriferous and colouring principles of most animal and vegetable substances. Thus, all saline substances, which, from the adherence of vegetable or animal extractive matter, are of a brown colour,—as crude tartar, crude nitre, impure carbonate of ammonia, and other salts,—may, after being digested through the medium of water with charcoal, be obtained white by a second crystallization. Resins, gum-resins, assafœtida, opium, balsams, essential oils, and many other substances, even those that have the strongest smell, are rendered nearly inodorous when they are rubbed with charcoal and water, or when solutions of them in alcohol are macerated with the charcoal, or filtrated repeatedly through it. A number of the vegetable tinctures and infusions also lose their colour, smell, and much of their taste, by the same process. Common vinegar, on being boiled with charcoal powder, becomes colourless. Malt spirit, by distil-

lation with charcoal, is freed from its disagreeable flavour. In the same manner wines also become colourless, and distilled waters lose their odours. Water, which, from having been long kept in wooden vessels, as during long voyages, has acquired an offensive smell, is deprived of it by filtration through charcoal powder, or even by agitation with it for a few minutes, especially when a few drops of sulphuric acid have also been added. Hence, also, it has been found that, by charring the inside of casks for keeping water, it may be preserved a long time without spoiling. Charcoal can even remove or prevent the putrescence of animal matter. If a piece of flesh has become tainted, the taste and smell may, in a great measure, be removed, by rubbing it with charcoal powder; and it may be preserved fresh for some time by burying it in the same substance. To produce these effects, however, it is necessary that the charcoal should have been well calcined and newly prepared.

The uses of charcoal are extensive. It is used as fuel in various arts, where a strong heat is required without smoke, as in dyeing, and in various metallurgic operations. By cementation with charcoal, iron is converted into steel. It is used in the manufacture of gunpowder, in its finer state of aggregation, under the form of ivory-black, lamp-black, &c. It is the basis of black paint; and mixed with fat oils and resinous matter, to give a due consistence, it forms the composition of printing ink. It is used to destroy colour and odour, particularly in syrups; to purify honey; to resist putrefaction; to confine heat, and for a number of other important purposes.

When charcoal is heated to a certain degree in the open air, or in oxygen gas, it takes fire, and burns with the production of an elastic vapour, which has been called *carbonic acid gas*. It is usually obtained, however, by other processes. It exists, combined with lime, in the different varieties of limestone, marble, and chalk; and if any of these substances be exposed to a strong heat, the affinity of the acid to the lime is so far weakened, that it assumes the elastic form, and may be collected. An easier mode is also practised for effecting its disunion, through the affusion of one of the more powerful acids. From the experiment of the direct formation of this acid, by the combustion of charcoal in oxygen gas, its composition has been determined to be 27.4 carbon, and 72.6 oxygen. Tennant illustrated its nature analytically, by passing the vapour of phosphorus over chalk, or the carbonate of lime, heated to redness in a glass tube. The phosphorus took oxygen from the carbonic acid, charcoal in the form of a light black powder, was deposited, and the phosphoric acid, which was formed, united with the lime. Carbonic acid is a colourless, inodorous, elastic fluid, which possesses all the physical properties of the gases in an eminent degree, and requires a pressure of 36 atmospheres to condense it into a liquid. Its specific gravity, compared with common air, is 1.5277. It extinguishes burning substances of all kinds, and is incapable of supporting the respiration of animals, its presence, even in a moderate proportion, being soon fatal. An animal cannot live in air which contains sufficient carbonic acid for extinguishing a lighted candle; and hence the practical rule of letting down a burning taper into old wells or pits, before any one ventures to descend. When an attempt is made to inspire pure carbonic acid, a violent spasm of the glottis takes place, which prevents the gas from entering the lungs. If it be so much diluted with air, as to admit of its passing the glottis, it then acts as a narcotic poison on the system. It is this gas which so often proves destructive to persons sleeping in a confined room with a pan of burning charcoal. Lime-water becomes turbid when brought into contact with carbonic acid, from the union of the lime with the gas, and the insoluble nature of the compound thus formed. Hence, lime-water is not only a valuable test of the presence of carbonic acid, but is frequently used to withdraw it altogether from any gaseous mixture that contains it. Carbonic acid is absorbed by water. Recently-boiled water dissolves its own volume of carbonic acid, at the common temperature and pressure; but it will take up much more if the pressure be increased. Water and other liquids, which have been charged with carbonic acid under great pressure, lose the greater part of the gas when the pressure is removed. The effervescence which takes place on opening a bottle of ginger beer, cyder, or brisk champaign, is owing to the escape of carbonic acid gas. Water which is fully saturated with carbonic acid gas sparkles when it is poured from one vessel to another. The solution has an agreeably acidulous taste, and gives to litmus paper a red stain, which is lost on exposure to the air. On the addition of lime-water to it, a cloudiness is produced, which at first disappears, because the carbonate of lime is soluble in an excess of carbonic acid; but a permanent precipitate ensues, when the free acid is neutralized by an additional quantity of lime-water. The water which contains carbonic acid in solution is wholly deprived of the gas by boiling. The agreeable pungency of beer, porter, and ale, is in a great measure owing to the presence of carbonic acid; by the loss of which, on exposure to the air, they become stale. All kinds of spring and well-water contain carbonic acid, which they absorb from the atmosphere, and to which they are partly indebted for their agreeable flavour. Boiled water has an insipid taste, from the absence of carbonic acid. Carbonic acid is always present in the atmosphere, even at the summit of the highest mountains. Its origin is obvious. Besides being formed abundantly by the combustion of all substances which contain carbon, the respiration of animals is a fruitful source of it, as may be proved by breathing a few minutes into lime-water. It is also generated in all the spontaneous changes, to which dead animal and vegetable matters are subject. The carbonic acid proceeding from such sources is commonly diffused equably through the air; but, when any of these processes occur in low, confined situations, as in the galleries of mines or in wells, the gas is then apt to accumulate there, and form an atmosphere called *choke damp*, which proves fatal to any animals that are placed in it. These accumulations take place only where there is some local origin for the carbonic acid; for example, when it is generated by fermentative processes going on at the surface of the ground, or when it issues directly from the earth, as happens at the Grotto del Cane, in Italy, and at Pyrmont, in Westphalia.

Though carbonic acid is the product of many natural operations, no increase of its quantity in the atmosphere is discoverable. Such an increase ap-

pears to be prevented by the process of vegetation. Growing plants purify the air by withdrawing carbonic acid, and yielding an equal volume of pure oxygen in return; but whether a full compensation for the deterioration of the air by respiration is produced in this way, has not as yet been satisfactorily determined.

Carbonic acid abounds in mineral springs, such as those of Tunbridge, Carlsbad, and Saratoga. In combination with lime, it forms extensive masses of rock, which occur in all countries, and in every formation. It unites with alkaline substances, and the salts so produced are called *carbonates*. Its acid properties are feeble, so that it is unable to neutralize completely the alkaline properties of potash, soda, and lithia. For the same reason all the carbonates, without exception, are decomposed by the muriatic and all the stronger acids; the carbonic acid is displaced, and escapes in the form of gas.

Another gaseous compound of carbon with oxygen, called *carbonic oxide*, exists, or may be obtained by heating powdered chalk, or any carbonate which can bear a red heat without decomposition, with iron filings in a gun-barrel. It is evolved together with carbonic acid gas, from which it may be freed by agitating the mixed gases with lime-water, when the carbonic acid is absorbed, and the gas in question is left in a state of purity. It is colourless and insipid. Lime-water does not absorb it, nor is its transparency affected by it. When a lighted taper is introduced into a jar of carbonic oxide, it takes fire, and burns calmly at its surface with a lambent, blue flame. It is incapable of supporting respiration. A mixture of 100 measures of carbonic oxide, and rather more than 50 of oxygen, on being exploded in Volta's eudiometer by electricity, disappear, and 100 measures of carbonic acid gas occupy their place; from which the exact composition of carbonic oxide is easily deduced: for carbonic acid contains its own bulk of oxygen; and, since 100 measures of carbonic oxide, with 50 of oxygen, form 100 measures of carbonic acid, it follows that 100 of carbonic oxide are composed of 50 of oxygen, united with precisely the same quantity of carbon as is contained in 100 measures of carbonic acid. Consequently, the composition of carbonic acid being,

By volume,
Vapour of carbon, 100
Oxygen gas, . . 100
100 carbonic acid gas,

By weight,
Carbon, ... 6
Oxygen, ... 16
22 carbonic acid,

that of carbonic oxide must be,

By volume,
Vapour of carbon, 100
Oxygen gas . . . 50
100 carbonic oxide gas,

By weight,
Carbon, ... 6
Oxygen, ... 8
14 carbonic oxide.

Its specific gravity is 0.9721.

The process for generating carbonic oxide will now be intelligible. The principle of the method is to bring carbonic acid, at a red heat, in contact with some substance which has a strong affinity for oxygen. This condition is fulfilled by igniting chalk, or any of the carbonates, with half its weight of iron filings, or of charcoal. The carbonate is reduced to its caustic state, and the carbonic acid is converted into carbonic oxide by yielding oxygen to the iron or the charcoal. When the first is used, an oxide of iron is the product; when charcoal is employed, the charcoal itself is converted into carbonic oxide.

CARBONIC ACID. See CARBON.

CARBONIC OXIDE. See CARBON.

CARBUNCLE, in *Surgery;* a roundish, hard, livid, and painful tumour, quickly tending to mortification, and (when it is malignant) connected with extreme debility of the constitution. When this complaint is symptomatic of the plague, a pestilential bubo usually attends it. (See PLAGUE.) The carbuncle is seated deeply, in parts provided with cellular membrane, and therefore does not soon discover its whole dimensions, nor the ill digested matter it contains.

CARCASS (in French, *carcasse*), in military language; an iron case filled with combustible materials, which is discharged from a mortar, like a bomb. There were formerly two kinds, oblong and round ones, but they are now out of use.

In architecture, *carcass* signifies the timber-work of a house, before it is either lathed or plastered.

CARCINOMA. See CANCER.

CARDIACUS PLEXUS, in *Anatomy*, is formed by the nerves which supply the heart, and which are derived from the superior and inferior cervical, and first dorsal ganglia of the great sympathetic nerve from the par vagum and the recurrent nerve.

CARDINAL POINTS; the four intersections of the horizon with the meridian and the prime vertical circle. They coincide with the four cardinal regions of the heavens, and are, of course, 90° distant from each other. The intermediate points are called *collateral points*.

CARDING; a preparation of wool, cotton, hair, or flax, by passing it between the iron points, or teeth, of two instruments, called *cards*, to comb, disentangle, and arrange the hairs or fibres thereof for spinning, &c. Before the wool is carded, it is coated with oil, whereof one-fourth of the weight of the wool is required for wool destined for the woof of stuffs, and one-eighth for that of the warp.

CARDS, PLAYING, are pieces of thin pasteboard, of an oblong figure, and with us commonly about 3½ inches long and 2½ broad; on which are printed a variety of points and figures; a certain number or assemblage of which serve for the performance of various games, as ombre, picquet, whist, &c. A full pack consists of fifty-two cards. The inventor of cards is not known, nor even the age when they first appeared; but judging from the material they were originally made of, viz. leaves of paper, they appear to be prior to the time of Charlemagne. The Hon. Daines Barrington, Mr. Bowles, and Mr. Gough, in their three essays on the "*Antiquity of Card-playing*," seem to agree that the Spaniards have the best pretensions to be considered as the original inventors of this amusement. Others have traced their invention to about the year 1390, for the purpose of diverting Charles VI., then king of France, who had fallen into a deep melancholy, and ascribe it to Jaquemin Gringonneur, a painter in Paris. Accordingly, in the accounts of the treasurer of that prince, the following article occurs: "Paid fifty-six shillings of

Paris, to Jaquenin Gringonneur, the painter, for three packs of cards gilded with gold, and painted with divers colours and divers devices, to be carried to the king for his amusement." From this item of account it appears, that the playing cards were originally very different in their appearance and price from what they are at present. They were gilt, and the figures were painted or illuminated, which required no little skill and genius, as well as labour. This last circumstance is one reason that playing cards were little known and used for several years after they were invented. By the four suits or colours, the inventor might design to represent the four states or classes of men in the kingdom. The *coeurs*, or hearts, denote the *gens de choeur*, choir-men or ecclesiastics. The nobility or principal military part of the kingdom is represented by the ends or points of lances or pikes, which, through ignorance of the meaning of the figure, we have called spades. By diamonds are designated the order of citizens, merchants, and tradesmen. The trefoil leaf, or clover grass, incorrectly called clubs, alludes to the husbandmen and peasants. The four kings are David, Alexander, Cæsar, and Charles, representing the four celebrated monarchs of the Jews, Greeks, Romans, and Franks, under Charlemagne. The queens represent Argine (for regina, queen by descent), Esther, Judith, and Pallas; which are typical of birth, piety, fortitude, and wisdom. The knaves denote the servants to the knights. The first certain notice of their having been known in England occurs in a record in the time or Edward IV. On an application of the card-makers of London to Parliament, A. D. 1463, an act was made against the importation of playing cards. From this statute it appears, that both card-playing and card-making were known and practised in England before this period, or about 50 years after the era of their supposed invention. Mr. Gough observes, that the use of cards among the Chinese is evident, not only from a Chinese painting, which represents their ladies playing at a game with something much thicker in substance than cards, yet shaped and numbered like them, but also from a pack of Chinese cards in his possession, made of the same materials as the European. However, the devices on the cards are very different from those known in this part of the world.

Careening (in French, *faire abattre, carèner*); heaving the vessel down on one side, by applying a strong purchase to the masts, so that the vessel may be cleansed from any filth which adheres to it by careening.

A *half careen* takes place when it is not possible to come at the bottom of the ship; so that only half of it can be careened.

Caribbee Bark. Under the general denomination of *cinchona*, several barks have been comprehended which are not the products of the real cinchona, and which, in fact, neither contain cinchona nor quinia, and cannot, consequently, be substituted as a febrifuge for the true species of cinchona. One of the principal substitutes of this kind is the Caribbee or St. Lucia bark, which is procured from the *exostema Caribæa* (Persoon), a tree growing in the West Indies. This bark is in convex fragments, covered with a yellow epidermis, commonly thin, but sometimes hard and spongy, with deep fissures, of a yellow, red, or brown tint internally, of a fibrous texture, offering here and there small shining and crystalline points of a very bitter taste and very faint smell.

Carminative, in *Medicine*; a denomination formerly applied to those articles of the materia medica which possess the property of dispelling wind from the stomach.

Carmine, the most splendid of all the red colours, is made from the cochineal insect, or *coccus cacti*. It is deposited from a decoction of powdered cochineal in water, to which alum, carbonate of soda, or oxide of tin, is added. As the beauty of this valuable colour is affected not only by the mode of applying it, but also by the quantity of the ingredients mixed with it, we find various recipes for the preparation of it. The manufactories which prepare the best carmine carefully conceal the method. The best natural cochineal is found in Mexico.

Carnation, in the *Fine Arts*; the colouring of the flesh of the human body. The use of carnation requires very attentive study and great skill in the artist. It varies with the sex of the individual, with the classes and countries to which the subjects belong, with the passions, the state of the health, &c. The cheeks are, in a healthy subject, of a lively red; the breast, neck, and upper part of the arms of a soft white; the belly yellowish. At the extremities the colour becomes colder, and at the joints assumes a violet tint, on account of the transparent appearance of the blood. All these shades require to be softly blended. Two faults in carnation are chiefly to be avoided—hardness, the fault of the masters of the 15th century, and too great weakness. Guido Reni not unfrequently painted his flesh so that it appeared almost bloodless. The French school has gone farthest in this respect. The flesh of the followers of this school often looks like porcelain or wax. Titian is still unrivalled in carnation.

Carotid, in *Anatomy*; a name given to the large arteries which supply the head, from a mistaken notion that tying these vessels would induce sleep.—There are two common carotid arteries, a right and left; of which the former is a arch of the arteria innominata, the latter arises from the branch of the aorta. Each of these vessels are again divided into an external and internal carotid artery.

Carpenter; an artificer in wood.

Carpentry; the art of employing timber in the construction of edifices. See Wood and Timber, manufactures connected with.

Carpets are thick textures, composed wholly or partly of wool, and wrought by several dissimilar methods. The simplest mode is that used in weaving Venetian carpets, the texture of which is plain, composed of a striped woollen warp on a thick woof of linen thread.

Kidderminster carpeting is composed of two woollen webs, which intersect each other in such a manner as to produce definite figures.

Brussels carpeting has a basis composed of a warp and woof of strong linen thread. But to every two threads of linen in the warp, there is added a parcel of about ten threads of woollen of different colours. The linen thread never appears on the upper surface, but parts of the woollen threads are from time to time drawn up in loops, so as to constitute ornamental figures, the proper colour being each time selected from the parcel to which it belongs. A sufficient number of these loops is raised to produce an uniform surface. To render them equal, each row passes

over a wire, which is subsequently withdrawn. In some cases the loops are cut through with the end of the wire, which is sharpened for the purpose, so as to cut off the thread as it passes out. In forming the figure, the weaver is guided by a pattern which is drawn in squares upon paper.

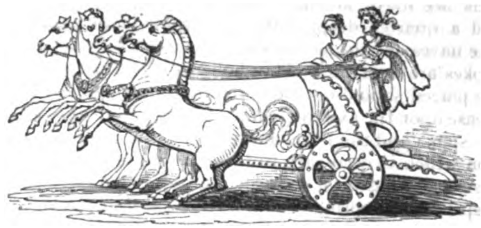
Turkey carpets appear to be fabricated upon the same general principles as the Brussels, except that the texture is all woollen, and the loops larger, and always cut. The English and Americans are the only nations among whom carpets are articles of general use.

CARRIAGE. The employment of wheel carriages may be traced to a very early period, and their usefulness principally arises from their power of diminishing friction. This important desideratum is effected by changing the rubbing motion of a sledge into the rolling motion of a cylinder. Thus wheels were probably at first but rollers. Whether their application to the removal of timber and heavy loads was accidental, or the invention of some early mechanic, is now but of little consequence to determine.

To improve these embryo germs of mechanism, and bring them into the form of wheels supporting a load upon an axletree, required a considerable degree of ingenuity; they must at first have been solid, the axletree must have been originally made of wood, and was probably fixed in the wheels, and moved round under the shafts or body of the carriage, as is common at present in the Irish car. The use of iron gudgeons, or iron axletrees, could not have been common in the first stages of civilization, and the separation of the wheels from the axletree was therefore of later date. Yet in the earliest authentic history which exists, chariots are mentioned as in use for pleasure, for war, and for carrying burthens.

Whilst carriages were used, where no regular roads had been made, the mechanical advantages of high and low wheels were not of consequence; the safety of the driver was the principal object. The height of the wheels was determined by the convenience of the warrior, and they were made of such a height as to permit him, encumbered with his armour, to ascend and descend with facility. We accordingly find in all ancient gems and monuments, that from the earliest antiquity the ancient war chariot had low wheels, the front part of the chariot high, to protect the warrior, the hinder part low and open, to permit him to mount and to descend easily; the pole was attached to the yoke that lay on the horse's withers, without any harness, but a collar round his neck, and two straps to hold it on. A metal chariot of a similar construction was dug up at Rome about the beginning of the present century.

As warriors generally employed more horses than were required for their weight and that of the car which bore them, there was no necessity for inquiry into the best form and size of wheels, or of any nicety in the means by which the horses were attached to the carriage. We read of no carriage drawn by one horse only, two horses were usually employed. In Homer, the chariots of Achilles and of other warriors appear to be drawn by two horses; but in some ancient gems it appears that chariots were drawn by four, six, and eight horses; and on one beautiful gem, in honour of a victor at the Olympic games, the chariot is drawn by twelve horses abreast. An engraved representation of an ancient carriage with horses will best illustrate their general form.



In coaches, and all other four-wheeled carriages, the fore-wheels are made of a less size than the hind ones, both on account of turning short, and to avoid cutting the braces: otherwise the carriage would go much easier if the fore-wheels were as high as the hind ones; and the higher the better, because they would sink to less depths in the small hollows in the roads, and be the more easily drawn out of them. But carriers and coachmen give another reason for making the fore-wheels much lower than the hind-wheels; namely, that when they are so, the hind-wheels help to push on the fore ones: which is, however, too unphilosophical and absurd to deserve a refutation.

In the preceding observations, we have supposed the rims of the wheels to be cylindrical. In concave wheels, however, the rims are uniformly made of a conical form, which not only increases the disadvantages that we have ascribed to them, but adds many more to the number. Mr. Cumming, in a valuable treatise on wheel carriages, solely devoted to the consideration of this single point, has shown, with great ability, the disadvantages of conical rims, and the propriety of making them cylindrical; but we are of opinion that he has ascribed to conical rims several disadvantages which arise chiefly from an inclination of the spokes. He insists much upon the injury done to the roads by the use of conical rims; yet, though we are convinced that they are more injurious to pavements and highways than cylindrical rims, we are equally convinced that this injury is occasioned chiefly by the oblique pressure of the inclined spokes. The defects of conical rims are so numerous and palpable, that it is wonderful how they should have been so long overlooked. Every cone that is put in motion upon a plane surface, will revolve round its vertex, and if force is employed to confine it to a straight line, the smaller parts of the cone will be dragged along the ground, and the friction greatly increased. Now when a cart moves upon conical wheels, one part of the cone rolls while the other is dragged along, and though confined to a rectilineal direction by external force, their natural tendency to revolve round their vertex occasions a great and continued friction upon the linchpin, the shoulder of the axletree, and the sides of deep ruts.

As the rims of wheels wear soonest at their edges, they should be made thinner in the middle, and ought to be fastened to the fellies with nails of such a kind, that their heads may not rise above the surface of the rim. In some military waggons, we have seen the heads of these nails rising an inch above the rims, which not only destroys the pavements of streets, but opposes a continual resistance to the motion of the wheel. If these wheels were eight in number, the wheel would experience the same resistance as if

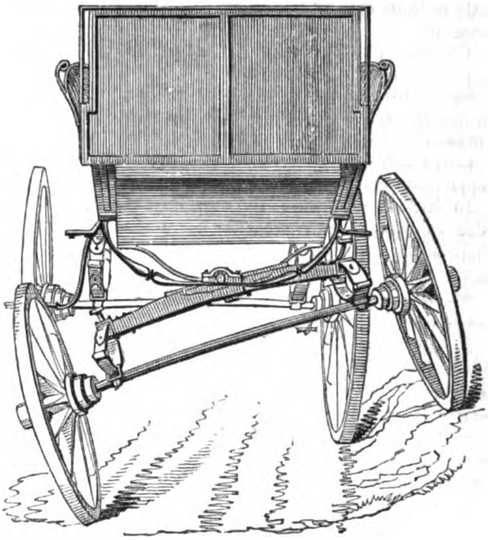
it had to surmount eight obstacles, one inch high, during every revolution. The fellies on which the rims are fixed, should in carriages be three inches and a quarter deep, and in waggons four inches. The naves should be thickest at the place where the spokes are inserted, and the holes in which the spokes are placed should not be bored quite through, as the grease upon the axletree would insinuate itself between the spoke and the nave, and prevent that close adhesion which is necessary to the strength of the wheel.

A coach has been defined, "a convenient carriage suspended on springs, and moving on four wheels," intended originally for the conveyance of persons in the upper circles of society, but now become very common among the middling classes in almost all civilized countries. The fashions, with regard to the form and ornament of coaches and other carriages for pleasure, are perpetually changing; the chief kinds now in use are, the close coach and chariot, the landau, which can lower its roof and part of its sides, like the head of a phæton; the barouche, or open summer carriage, made on the lightest construction; the chariot, which is intended only for two or three persons; the landaulet, or chariot whose head unfolds back; in addition to which there is the britscha, a carriage now very generally employed. These all run upon four wheels. Of the two-wheeled vehicles, there is the curricle, drawn by two horses, each bearing on a narrow saddle the end of a sliding-bar or yoke that upholds a central pole; the gig, chaise, or wiskey, that have each only one horse, which moves between a pair of shafts, borne nearly horizontally, by means of a leathern sling passing over the saddle-tree. When a gig, &c., has two horses, one preceding the other, in harness, the machine and its horses are, taken together, denominated a tandem. In addition to these we have a tilbury, a cabriolet, and a Stanhope.

Mr. Fuller has effected a considerable improvement on light four-wheel carriages, which is deserving of notice. It consists in the adaptation of an apparatus to the front part of the vehicle, which is designed to prevent the carriage from overturning, by preserving the body at all times in a horizontal position, even when one of the wheels accidentally passes over a large stone in the road, or up a bank by the road side, or any other obstruction which would overthrow a carriage built upon any of the ordinary plans at present in use.

The principle of this invention will perhaps be best understood, by first pointing out the difficulty with which four-wheeled carriages are drawn over impediments, or uneven roads. Stage coaches are particularly subject to this disadvantage, as will appear upon a slight view of these vehicles, which are usually made as follows:—The body part being intended to bear the weight of fifteen persons with luggage, must be very securely framed together, and consequently cannot admit of the least flexibility. The carriage, therefore, in accommodating itself to the unevenness of the roads, must frequently run upon three wheels, and thereby be subjected to very considerable strain; for it is evident, that if one corner be raised by a wheel passing over a stone, or any other sudden rise in the road, that one half of the carriage will be raised at the same time, and the whole weight of that half so lifted will be supported by the elevated wheel, and its axle and springs at the corner, which passes over the obstacle; the spring being thereby greatly depressed. Each wheel, axle, and spring, therefore is occasionally required to support double the weight that they are designed to carry; and this being thrown upon them suddenly, renders it necessary to construct those parts of the carriage of double the strength that would otherwise be thought desirable.

The present invention is intended to remove this disadvantage, which will be better understood by an engraving.

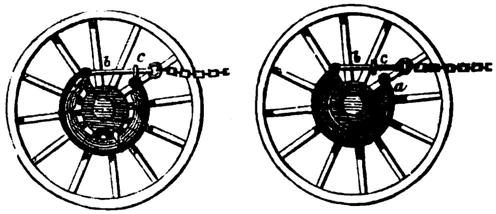


A circular horizontal locking-wheel, formed of iron, is attached to the front part of the carriage. This bears upon the axletree bed and upon segments supported by iron arms, and is enabled to turn round horizontally upon these bearings in the act of locking; the axletree bed itself being attached to, and supported by the front springs. A bar crosses the middle of the locking-wheel, and is attached to it by ears and bolts, the centre of this bar having a circular hole, through which a pin passes for the purpose of forming the pivot or axle on which the locking-wheel turns. The extremities of the bar, which extend beyond the wheel, are made truly cylindrical, and to these are attached the plummer-boxes, or gudgeons, from whence the bent arms extend for the purpose of supporting the front part of the body of the carriage, as seen in the figure.

It will now be perceived, that in the event of one of the fore-wheels running over a large stone, or any other elevated obstruction in the road, the axletree will be thrown out of its horizontal position; but the body of the carriage in front being supported solely upon the pivots at the ends of the bar, the plummer-boxes will turn upon the pivots, and cause the bent arms to keep the body of the carriage in its erect position, although one of the fore-wheels is raised up so considerably.

A very ingenious *drag* for vehicles descending hills has been contrived by Mr. Rapson, which is well worthy of notice. This drag is to be applied to the naves of the carriage wheels, with a chain attached, fastened to the breeching of the horse, and a small pin on each side of the shaft is to go into the bar of the drag. If one of these pins be taken out, the

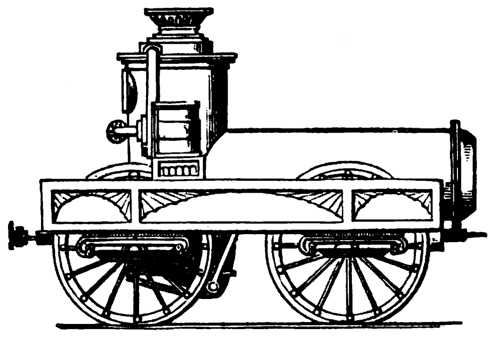
wheel will be dragged, but the other will of course turn freely; and by leaving out both pins, the wheels are acted upon in conjunction, during the descent, by the breech bearing against the horse.



In the first of these diagrams we have a representation of the break attached to the carriage, but inoperative; as it will be seen that the chain *c*, and bolt *b*, admit the jointed circle to remain at some distance from the nave of the wheel.

In the second figure, the entire frame, *a, b, c*, are seen in direct collision with the nave, and act by their friction to retard the wheel; this, however, does not occur till the breeching of the harness is drawn tight by the descent of the carriage on an inclined road.

We have now to notice a form of vehicle which under most circumstances seems likely to supersede those now in use. We need hardly add, that we allude to the carriage propelled by steam; an engraving of one of these vehicles, copied from Mr. Gordon's valuable treatise on locomotion, may be found interesting.



Dr. Darwin, in the spirit of prophecy, more than half a century back, predicted such an event. His words are—

> "Soon shall thine arm, unconquered steam, afar
> Drag the slow carriage, and impel the rapid car;
> Or on wide-waving wings expanded bear
> The flying chariot through the fields of air."

Now the steam-boat and steam-carriage have already been placed in practical operation; and Sir George Cayley, in a very ingenious paper in the *Philosophical Magazine*, furnishes data which show the aerial carriage to be any thing but wild or visionary.

Carriages of this description vary very considerably in their weight, from four or five tons, down to as many ounces. The Editor of this work has one which goes at the rate of nine miles per hour on a level road, and yet weighs less than one pound. He possesses another, which is under the entire controul of the conductor, carries two persons, and weighs less than one hundred weight; so that the enormous mass of iron now generally employed in these vehicles, may be reduced to a great extent. It may be proper to add, that a vehicle of this description is now exhibiting in London, weighing *five tons!* The possibility of their general employment on common roads has now ceased to be problematic; and there is no doubt but that we shall be enabled to congratulate our readers on their complete success, when describing their mechanical structure, under the article STEAM CARRIAGES.

CARRONADES (from the river *Carron*, in Scotland, where they were first made); a sort of artillery resembling howitzers. They are of very large caliber, and carry balls, shells, or cartouches. They are much lighter than common cannon, and have a chamber for the powder like mortars. They are mostly used on board of ships in close engagements, from the poop and forecastle. Sometimes they are employed in fortifications. They have been cast from 12 to 68 pounders. They were first used in the North American revolutionary war.

CART. See CARRIAGE.

CARTILAGE is a semi-pellucid substance, of a milk-white or pearly colour, entering into the composition of several parts of the body. It holds a middle rank, in point of firmness, between bones or hard parts, and the softer constituents of the human frame. It appears, on a superficial examination, to be homogeneous in its texture; for when cut, the surface is uniform, and contains no visible cells, cavities, nor pores, but resembles the section of a piece of glue. It possesses a very high degree of elasticity, which property distinguishes it from all other parts of the body. Hence it enters into the composition of parts whose functions require the combination of firmness with pliancy and flexibility, the preservation of a certain external form, with the power of yielding to external force or pressure. Anatomists divide cartilages into two kinds, the *temporary* and the *permanent*. The former are confined to the earlier stages of existence; the latter commonly retain their cartilaginous structure throughout life. The *temporary cartilages* are those in which the bones are formed. All the bones except the teeth are formed in a *nidus* of cartilage. The *permanent cartilages* are of various kinds. They compose the external ear and external aperture of the nostrils and eyelids. The larynx is formed entirely of this substance, and the trachea or windpipe, with its branches, is furnished with cartilaginous hoops, by which these tubes are kept permanently open for the ready passage of air to and from the lungs.

The bodies of the vertebræ are joined by large masses of a peculiar substance, partaking of the properties and appearance of cartilage and ligament, which allow of the motions of these parts on each other, without weakening the support that is afforded to the upper parts of the body in general, and to the head in particular, by the vertebral column. These cartilages impart great elasticity to the spine, by which the effects of concussion from jumping, from falls, &c., are weakened and destroyed before they can be propagated to the head. When the body has been long in an erect position, the compression of these cartilages, by the superior parts, diminishes the height of the person. They recover their former length when freed from this pressure. Hence a person is taller when he rises in the morning, than after sustaining the fatigues of the day, and the difference has sometimes amounted to an inch. Cartilages are

sometimes interposed between the articular surfaces of bones, where they fill up irregularities that might otherwise impede the motions of the part, and increase the security of the joint by adapting the articular surfaces to each other. These surfaces are in every instance covered by a thin crust of cartilage, having its surface most exquisitely polished, by which all friction in the motions of the joint is avoided.

CARTOON has many significations. In painting, it denotes a sketch on thick paper, pasteboard, or other material, which is used as a model for a large picture, especially in fresco, oil, tapestry, and formerly in glass and mosaic. In fresco painting, cartoons are particularly useful; because in this a quick process is necessary, and a fault cannot easily be corrected. In applying cartoons, the artist commonly traces them through, covering the back of the design with black lead or red chalk; then laying the picture on the wall or other matter, he passes lightly over each stroke of the design with a point, which leaves an impression of the colour on the plate or wall; or the outlines of the figures are pricked with a needle, and then the cartoon being placed against the wall, a bag of coal-dust is drawn over the holes, in order to transfer the outlines to the wall.

In fresco painting, the figures were formerly cut out, and fixed firmly on the moist plaster. The painter then traced their contour with a pencil of wood or iron; so that the outlines of the figures appeared on the fresh plaster, with a slight but distinct impression, when the cartoon was taken away. In the manufacture of a certain kind of tapestry, the figures are still cut out, and laid behind or under the woof, by which the artist directs his operations. In this case the cartoons must be coloured. Of this kind are the cartoons which Raphael executed for Pope Leo X., from which the famous tapestries of Raphael in the Netherlands were woven. There were twelve of them, representing histories taken from the New Testament. Seven of them are still extant, and may be seen at Hampton Court palace. Rubens bought these cartoons for Charles I., and King William built a gallery for them at Hampton Court. The cartoon of the School of Athens, carried to Paris by the French, and a fragment of the Battle of Maxentius and Constantine, are preserved in the Ambrosian Gallery at Milan. There are likewise cartoons by Giulio Romano in the Sala Borgia, by Domenichino and other Italian masters, who caused their pictures to be executed, in a great degree by their scholars, after these cartoons.

The value set upon cartoons by the old Italian masters may be seen by Giov. B. Armenini's *Precetti della Pittura*. In later times, large paintings, particularly in fresco, were not executed so frequently. The artists also laboured with less care, and formed their great works more from small sketches. In modern times, some German artists have prepared accurate cartoons. Among them is Cornelius, whose cartoons, for his fresco paintings in Münich, have acquired much celebrity. He prepared, too, a cartoon for the fresco picture representing *Joseph interpreting the Dream*. Overbeck also has made cartoons, from which he has painted the *Seven Years of Famine*, and the *Selling of Joseph*. The *Seven Years of Plenty* he executed, with the assistance of William Schadow and Philip Veit. The representations of Joseph's history, just mentioned, the late Prussian consul-general Bertholdy has caused to be executed in fresco, at his residence in Rome, by the above-named artists. For the villa Massimi, near Rome, Overbeck has prepared cartoons representing scenes from Tasso's *Jerusalem Delivered;* Julius Schnorr, illustrations of Ariosto, and Veit, scenes taken from Dante.

CARTOUCH, in *Architecture, Sculpture*, &c., denotes an ornament representing a scroll of paper, being usually in the form of a table, or flat member, with wavings, whereon is some inscription or device.

In Heraldry; a name given to a sort of oval shields, much used by the popes and secular princes in Italy, and others, both clergy and laity, for painting or engraving their arms on.

In the Military Art; a wooden case, about three inches thick at bottom, and girt round with marline, holding 2, 3, or 400 musket balls, with 8 or 10 iron balls, weighing one pound each, to be fired from a mortar, gun, or howitzer, for the defence of a pass, retrenchment, &c. It is also used for a cartridge-box, now employed mostly by the infantry. The charge of a cannon is also sometimes called by this name.

Cartouche is likewise the name given by the French literati to that oval ring or border which includes, in the Egyptian hieroglyphics, the names of persons of high distinction, as M. Champollion has proved. This border was thought at first, by Zoëga, to include every proper name.

CARTRIDGE; a case of paper, parchment, or flannel, fitted to the bore of fire-arms, and filled with gunpowder, to expedite the discharge of the piece. Cartridges are of two sorts, viz. *ball*-cartridges, used in firing balls, and *blank*-cartridges, used in firing without ball. Riflemen avoid the use of cartridges, because the cartridge injures the shot of a rifle. In most armies, a soldier carries 60 cartridges into battle.

CARVER; a cutter of figures or devices in wood.

CARYATIDES. See ARCHITECTURE.

CASE-HARDENING is a process by which iron is superficially converted into steel, in such articles as require the toughness of the former, conjointly with the hardness of the latter substance. The articles intended for case-hardening are first manufactured in iron, and are then placed in an iron box, with vegetable or animal coals in powder, to undergo cementation. Immersion of the heated pieces into water hardens the surface, which is afterwards polished. Coarse files and gun-barrels are among the articles most commonly case-hardened.

CASEMATES (from the Spanish *casa*, a house, and *matare*, to kill), in fortification; vaults which are proof against bombs, under the main wall, particularly in bastions, for the purpose of defending the moat of a fortification, also for making countermines. They serve at the same time as a place for keeping the heavy ordnance, and in case of necessity, as habitations for the garrison.

CASE-SHOT, in artillery, is formed by putting a quantity of small iron balls into a cylindrical tin box, called a *canister*, that just fits the bore of the gun. In case of necessity, the canister is filled with broken pieces of iron, nails, stones, &c. The case is closed at both ends by wood. Shot of this sort are thrown from cannons and howitzers. In sieges, sometimes, instead of cases, bags are used. This kind of shot is very injurious to the enemy, because

the balls contained in the canister spread, diverging in proportion to the distance. The amount of divergence is, to the distance which the shot reaches, generally in the proportion of 1 to 10; thus, at the distance of 600 paces, they make a circle of 60 paces diameter. The canisters used in the Prussian army contain balls of 1, 1½, 3, 4, 6, 8, and 12 ounces, and of 1 pound. The distance which the shot will reach varies according to the weight and number of the balls. A six-pounder shoots canister balls of 1 ounce from 200 to 500 paces; twelve and twenty-four-pounders shoot balls of 1 pound 800 to 1000 paces. The number of the balls varies according to their weight.

CASQUE; a defensive armour for covering the head and neck. The king had one gilt with gold; the dukes and counts had theirs with silver; gentlemen of high extraction wore theirs of polished steel, and the rest of plain iron. The Romans had their casques of brass or iron, which were proof against the strokes of any sword or sabre, and were ornamented to the height of two feet with plumes of feathers, or tufts of horse hair, of different colours. The chiefs and principal officers wore casques gilt and enriched with precious stones, with the tops of them ornamented with plumes and aigrettes of great value, which served to distinguish them from others. The Scandinavians, and other people of the North, used to wear them, and their invention is ascribed by some to the Scythians and the Celts.

CASSINO; a game at cards, in which four are dealt to each player, four being also placed on the board. The object is to take as many cards as possible, by making combinations. Thus, a ten in the player's hand will take a ten from the board, or any number of cards which can be made to combine into tens. The greatest number of cards reckons three points, and of spades, one; the ten of diamonds, two; the two of spades, one; and each of the aces, one.

CASSIOPEIA, in *Astronomy*, is a conspicuous constellation in the northern hemisphere, situated next to Cepheus. In 1572, a new and brilliant star appeared in it, which, however, after a short time gradually diminished, and at last disappeared entirely. It was thought at that time, by many persons, that this was the star which appeared to the wise men in the East. The constellation Cassiopeia contains 52 stars of the first six magnitudes.

CASTANETS; small wooden rattles, made in the shape of two bowls or cups, fitted together, and tied by a string, and then fastened to the thumbs. The fingers being rapidly struck upon them, a tremulous sound is produced, which marks exactly the measure of the dance. Something similar to this was the *crotalon* of the ancients, who also made use of small cymbals in their dances and festivals in honour of Bacchus. It is probable, however, that they had their origin in the East, and were brought by the Moors into Spain. Here, too, they received their name *castanuelas*, from being commonly made of the wood of the chestnut (*castano*), or from their colour. They are still in use in Spain, and here and there in the south of France. The charm of variety has also procured for them a place in ballets and operas, where they have now become general.

CAST ENGRAVINGS An important discovery has lately been made, which consists in taking moulds from every kind of engraving, whether line, mezzotinto, or aquatinta, and in pouring on this mould an alloy in a state of fusion, capable of taking, as it is stated, the finest impression. No sooner is one cast worn out, than another may immediately be procured from the original plate, so that every impression may be a proof. (See STEREOTYPE.)

CASTING. Iron, as well as brass, and other metals which melt at temperatures above ignition, is cast in moulds made of sand. The kind of sand most employed is loam, which possesses a sufficient portion of argillaceous matter to render it moderately cohesive when damp. The mould is formed by burying in the sand a wooden pattern, having exactly the shape of the article to be cast. The sand is most commonly enclosed in flasks, which are square wooden frames, resembling boxes, open at top and bottom. If the pattern be of such form that it can be lifted out of the sand without deranging the form of the mould, it is only necessary to make an impression of the pattern in one flask; and articles of this kind are sometimes cast in the open sand upon the floor of the foundry. But when the shape is such that the pattern could not be extracted without breaking the mould, two flasks are necessary, having half the mould formed in each. The first flask is filled with sand, by ramming it close, and is smoothed off at the top. The pattern is separated into halves, one half being imbedded in this flask. A quantity of white sand, or burned sand, is sprinkled over the surface, to prevent the two flasks from cohering. The second flask is then placed upon the top of the first, having pins to guide it; the other half of the pattern is put in its place, and the flask is filled with sand, which of course receives the impression of the remaining half of the pattern on its under side. After one or more holes are made in the top, to permit the metal to be poured in and the steam and air to escape, the flasks are separated and the pattern withdrawn. When the flasks are again united, a perfect cavity or mould is formed, into which the melted metal is poured. The arrangement of the mould is of course varied for different articles.

When the form of the article is complex and difficult, as in some hollow vessels, crooked pipes, &c., the pattern is made in three or more pieces, which are put together to form the mould, and afterwards taken apart to extract them. In some other irregular articles, one part is cast first, and afterwards inserted in the flask which is to form the other part. The metal for small articles is usually dipped up with iron ladles coated with clay, and poured into the moulds. In large articles, such as cannon, the mould is formed in a pit dug in the earth near the furnace, and the melted metal is conveyed to it in a continued stream, through a channel communicating with the bottom of the furnace.

Cannon-balls are sometimes cast in moulds made of iron, and to prevent the melted metal from adhering, the inside of the mould is covered with powder of black lead. Rollers for flattening iron are also cast in iron cases. This method is called *chill casting*, and has for its object the hardening of the surface of the metal by the sudden reduction of temperature, which takes place in consequence of the superior conducting power of the iron mould. These rollers are afterwards turned smooth in a powerful lathe, which has a slow motion, that the cutting tool may not become heated by the friction.

Casting in Plaster. Copies are most frequently taken, both from new models and from old statues,

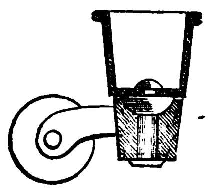
by casting them in plaster. For this purpose a mould in plaster is first made from the surface of the statue or figure itself; and this mould is afterwards used to reproduce the figure by casting. Plaster is prepared for use by pulverizing common gypsum, and exposing it to the heat of a fire until its moisture is wholly expelled. While in this dry state, if it be mixed with water to the consisience of cream or paste, it has the property of hardening in a few minutes, and takes a very sharp impression. The hardness afterwards increases by keeping, till it approaches the character of stone. Moulds are formed in the following manner:—The statue or figure to be copied is first oiled, to prevent it from cohering with the gypsum. A quantity of liquid plaster sufficient for the mould is then poured on immediately after being mixed, and suffered to harden. If the subject be a bass-relief, or any figure which can be withdrawn without injury, the mould may be considered as finished, requiring only to be surrounded with an edging. But if it be a statue, it cannot be withdrawn without breaking the mould; and on this account it becomes necessary to divide the mould into such a number of pieces as will separate perfectly from the original. These are taken off from the statue, and when afterwards replaced, or put together without the statue, they constitute a perfect mould. This mould, its parts having been oiled to prevent adhesion, is made to receive a quantity of plaster, by pouring it in at a small orifice. The mould is then turned in every direction in order that the plaster may fill every part of the surface; and when a sufficient quantity is poured in to produce the strength required in the cast, the remainder is often left hollow, for the sake of lightness and economy of the material. When the cast is dry, it is extricated by separating the pieces of the mould, and finished by removing the seams and blemishes with the proper tools. If the form or position require it, the limbs are cast separately, and afterwards cemented on.—Moulds and busts are obtained in a similar manner from living faces, by covering them with new plaster, and removing it afterwards as soon as it becomes hard. It is necessary that the skin of the face should be oiled; and during the operation the eyes are closed, and the person breathes through tubes inserted in the nostrils. Elastic moulds have been formed by pouring upon the figure to be copied a strong solution of glue. This hardens upon cooling, and takes a fine impression. It is then cut into suitable pieces, and removed. The advantage of the elastic mould is, that it separates more easily from irregular surfaces, or those with uneven projections and under-cuttings, from which a common mould could not be removed without violence. For small and delicate impressions in relief, melted sulphur is sometimes used; also a strong solution of isinglass in proof spirit.

Bronze Casting. Statues intended to occupy situations in which they may be exposed to violence, are commonly made of bronze. This material resists both mechanical injuries and decay from the influence of the atmosphere. The moulds in which bronze statues are cast are made on the pattern, out of plaster and brick-dust, the latter material being added to resist the heat of the melted metal. The parts of this mould are covered on their inside with a coating of clay, as thick as the bronze is intended to be. The mould is then closed and filled on its inside with a nucleus or core of plaster and brick-dust, mixed with water. When this is done, the mould is opened and the clay carefully removed.—The mould, with its core, is then thoroughly dried, and the core secured in its central position by short bars of bronze, which pass into it through the external part of the mould. The whole is then bound with iron hoops, and when placed in a proper situation for casting, the melted bronze is poured in through an aperture left for the purpose: of course the bronze fills the same cavity which was previously occupied by the clay, and forms a metallic covering to the core. This is afterwards made smooth by mechanical means.

Castor, the produce of the beaver. In the body of this animal are found four bags, a large and a small one, on each side; in the two large ones there is contained a softish, grayish, yellow, or light-brown substance, which, on exposure to the air, becomes dry and brittle, and of a brown colour. This is castor. It has a heavy but somewhat aromatic smell, not unlike musk; and a bitter, nauseous, and sub-acid taste. The best comes from Russia; but of late years it has been very scarce, and all that has been found in the shops is the produce of Canada. The goodness of castor is determined by its sensible qualities; that which is black is insipid, inodorous, oily, and unfit for use. Castor is said to be sometimes counterfeited by a mixture of some gummy and resinous substances; but the fraud is easily detected by comparing the smell and taste with those of real castor.

Castor; a friction-wheel placed beneath tables and other weighty articles of furniture to facilitate their removal. We notice the castor to point out a patent improvement of considerable importance by Mr. Geithner.

The improvement proposed is designed to give stability to the stem of the castor, and to enable it to turn upon its pin with less friction than those of the ordinary construction. This is effected by making the upper part of the vertical pin on which the socket of the roller carriage turns broad and partly spherical, which spherical part acts in a corresponding recess in the upper part of the socket of the roller carriage.



In the engraving is represented a section of the complete castor; at the top is the socket, into which the foot of the piece of furniture is inserted as usual; in this is placed the vertical pin riveted into the socket, upon which the carriage of the roller turns. The upper part of this pin, it will be seen, is enlarged and made in a convex form, which fits into the concave part of the stem of the roller carriage, and the pin and roller carriage being attached and secured by a nut or rivet, the carriage is enabled to turn round upon the pin with a very firm bearing, and with very little friction. The patentee does not confine himself precisely to this construction, but sometimes forms the convex part of the pin upwards, and causes it to act in a corresponding recess in the under part of the socket, which answers the purpose equally well.

Castor-Oil. The castor-oil plant (*ricinus palma Christi*) is a native both of the East and West Indies, and has a stem from 5 to 15 or 16 feet in height, and large, bluish-green leaves, divided into 7 lobes,

serrated and pointed, the foot-stalks long, and inserted into the disk. The flowers are produced in a terminating spike, and the seed-vessels are covered with spines, and contain three flattish, oblong seeds. it is to the seeds of this plant that we are indebted for the drug called *castor-oil*. It is now often prepared by pressing the seeds in the same way as is practised with oil of almonds. The oil thus obtained is called *cold expressed*. But the mode chiefly adopted in the West Indies is first to strip the seeds of their husks or pods, and then to bruise them in mortars. Afterwards they are tied in linen bags and boiled in water until the oil which they contain rises to the surface. This is carefully skimmed off, strained, to free it from any accidental impurities, and bottled for use. The oil which is obtained by boiling is considered more mild than that procured by pressure, but it sooner becomes rancid. The mildest and finest Jamaica castor-oil is very limpid, nearly colourless, and has scarcely more smell or taste than good olive-oil. Many people, however, have so great an aversion to castor-oil, even in its purest state, that they do not take it without great reluctance. The uses of castor-oil in medicine are well known; and it is exceedingly valuable as a mild and safe purgative. It is principally employed for children.

CASTRAMETATION; strictly, the art of tracing out and disposing to advantage the several parts of a camp on the ground. It is sometimes used more extensively to include all the ordinary operations of a campaign. A camp, whether composed of tents or barracks, or merely of places assigned for bivouacking, must be divided in such a way that the several divisions shall be disposed as they are intended to be when drawn up in order of battle; so that on a sudden alarm the troops may rise in their proper posts. At the same time the places for cooking, for the baggage, and for ammunition, must be conveniently arranged.

CASTRATION. See EMASCULATION.

CATACOUSTICS, called also *cataphonics*; the science of reflected sounds, or that part of acoustics which considers the properties of echoes.

CATALEPSY. This is a spasmodic disease, and by some regarded as a species of *tetanus*. It affects the whole body so as to render it immoveable, as if dead. *Tetanus* differs from *catalepsy* in its subjects and causes. Females are most liable to the last, while the first is equally produced in both sexes by appropriate causes. Tetanus is most frequently produced by punctured wounds of tendinous textures, and most readily in hot weather. Sometimes, however, it occurs like catalepsy, independently of wounds. The spasm is more limited in tetanus; sometimes being most severe in the muscles of the face, producing lock-jaw; now it attacks the muscles of the trunk on the fore part, producing *emprosthotonos*, and then the muscles of the back part, producing *opisthotonos*, or curvature of the trunk backwards. During all this the natural temperature may remain, the pulse be perfectly natural, and the senses unimpaired. Under the most active and varied treatment tetanus has always been a very fatal malady.

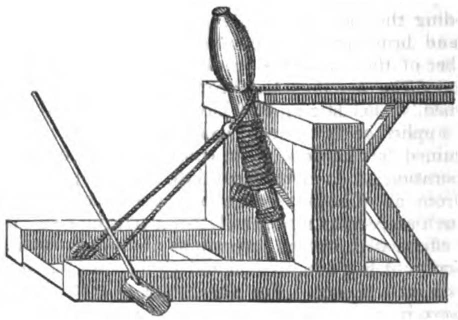
Catalepsy is an universal spasmedic disease of the organs of locomotion. The body remains in the position in which it may have been when attacked with the fit, and the limbs preserve any situation in which they may be placed. The senses are oblitерated, and the mind totally inactive, nothing being able to rouse the patient. The pulse and temperature remain natural. The fit is of uncertain length; according to some writers, not lasting more than a quarter of an hour, though known by others to be much longer. This disease is an obstinate one, and is very liable to recur, even when the patient seems in the least respect liable to a recurrence. It is, for the most part, a consequence of some other disease. This may be a local affection; but it more frequently occurs in a generally enfeebled constitution, induced by some dangerous malady, or one which has been caused by the gradual operation of unobserved morbid causes.

CATAMENIA. See MENSES.

CATAPELTA; an instrument of punishment in use among the ancients. It consisted of a press, composed of planks, between which the criminal was crushed to death.

CATAPLASMS, or POULTICES, are soft compounds, intended to be applied to the surface of the body.—They are commonly made of meal, boiled pulp, mixed with water, milk, or some other liquid. They are called *sinapisms* when mustard forms their base.

CATAPULTS; certain machines of the ancients, corresponding to our heavy cannon. The catapults differed from the *ballistæ* by throwing more horizontally, the latter more in a curve. The whole machine rested on a frame, and, if intended for the field, had wheels. The size of these machines varied much. The large catapults shot arrows of 3 cubits, or 4½ Roman feet, in length, often larger ones, and sometimes beams 12 feet long. Burning arrows were likewise often thrown by the catapults. The large ones threw their arrows 4 stadia, but not more than 2 stadia with precision. Pliny ascribes the invention of catapults to the Syrians; Plutarch and Diodorous, to other nations. A catapult of a very powerful kind is shown in the figure. From its structure it might be employed either for arrows or round stones.



At the siege of Jerusalem, the Romans had 300 catapults and 40 ballistæ. The Romans did not carry all the parts of these machines with them, but only the ropes and fastenings, with the necessary tools; and the soldiers built the catapults when they wanted them. The terms *catapult* and *ballistæ* were often used indiscriminately; and in later times, the word *catapult* went entirely out of use. Vegetius and Ammianus Marcellinus never introduce it, and employ *ballistæ* to signify all machines throwing large arrows or beams, and *onager* for those throwing stones.

CATARACT. By this term two very different dis-

cases are designated by some writers, viz., the true *cataract*, and *amaurosis*, or *gutta serena*. By the first of these terms, in its most common signification, is understood opacity of the crystalline lens, or its capsule, or both. By the second is meant a disease of the retina, by which it is rendered unsusceptible of the action of light. In cataract, the lens becomes opaque, loses its transparency, and is no longer capable of transmitting the light. The causes of cataract are numerous. Inflammation may produce it. Sometimes it is ascribed to a state of the vessels of the part which prevents a proper nourishment of the lens or its capsule. It is produced by various diseases, such as gout, rheumatism, scrofula, and accompanies old age. Its earliest approach is marked by a loss of the natural colour of the pupil; this becoming turbid, or slightly gray. *Muscæ volitantes* accompany this period. The opacity is not at first over the whole crystalline, and most frequently, first attacks the centre portion; this being turbid, and of a grayish colour, while the surrounding portions remain transparent, and of the usual black colour. While it exists in this degree only, the person can see in an oblique direction. The colour of the pupil is various; mostly grayish-white or pearl-coloured; sometimes milk-white, or of a yellowish-gray; now and then of a grayish-brown, and even of a dark-brown or dark-gray. The consistence of the lens differs in different cases, being either hard, and even horny, or very soft, as if dissolved.

The treatment of cataract is by a surgical operation on the eye, and different operations have been tried and recommended. They all consist in removing the diseased lens from its situation opposite the transparent cornea. By one of these operations the cataract is *depressed*, removed downwards, and kept from rising by the vitreous humour. This is called *couching*. Another operation is *extraction*, and consists in making an incision of the cornea, and of the capsule of the lens, by which the lens may be brought forward, and through the cut in the cornea. The third operation is by *absorption*. This consists in wounding the capsule, breaking down the crystalline, and bringing the fragments into the anterior chamber of the eye, where they are exposed to the action of the aqueous humour, and are at length absorbed. This last operation has the name *keratonyxis* applied to it. The choice of the operation is determined by the character of the cataract. After the operation, the patient is to be kept from the light, and from all means of irritation. Such medicines and such articles of food are to be prescribed as will most effectually prevent inflammation; and should this occur, it must be treated by such means as are the most sure to restrain or overcome it.

Amaurosis is a disease of the optic nerve, and its continuation, the retina. Its causes are numerous. It may be occasioned by organic disease of the parts referred to, by mechanical pressure upon the nerve, by too powerful light, by long-continued use of the eyes in too weak light, by rapid transition from darkness to light, and finally by old age. Various other, and some more general, causes may produce amaurosis. Among these are wounds of the head, compression of the brain, fits of apoplexy, suppressed colds in the head, habitual inebriety, vomiting, coughing, sneezing, affections of the alimentary canal, and some of the neighbouring viscera—the liver, for example. According to the activity of these various causes, the malady comes on suddenly or gradually. The patients are sometimes unable to bear the light, and therefore seek the darkness, where sparks and flames frequently appear to their eyes. Objects sometimes appear of different colours, or fluctuate, swim, and confuse themselves. At other times, the patients begin to squint, suffer a severe pain in the ball of the eye, and a straining above the eyebrows: finally, they begin to see as if through a crape or fog, and only in bright daylight can distinguish accurately: black flakes and specks appear to hover before their eyes. The greatest insensibility of the retina is often opposite the centre of the cornea; but ultimately the disease produces total blindness, the pupil losing its motion, and becoming permanently dilated. Deep in the eye a white speck is often visible, which is traversed by veins. According to the different causes, the malady is either easily cured or is incurable. Regard is especially to be had to them in the selection and use of remedies.

CATARRH; an increased secretion of mucus from the membranes of the nose, fauces, and bronchia, accompanied with fever, and attended with sneezing, cough, thirst, lassitude, and want of appetite. There are two species of catarrh, viz., *catarrhus à frigore*, which is very common, and is called a *cold in the head*; and *catarrhus à contagio*, the influenza, or epidemic catarrh, which sometimes attacks a whole city. Catarrh is also symptomatic of several other diseases. It is seldom fatal, except in scrofulous habits, by laying the foundation of phthisis; or where it is aggravated, by improper treatment, or repeated exposure to cold, into some degree of peripneumony; when there is hazard of the patient, particularly if advanced in life, being suffocated by the copious effusion of viscid matter into the air-passages. The epidemic is generally, but not invariably, more severe than the common form of the disease. The latter is usually left to subside spontaneously, which will commonly happen in a few days, by observing the antiphlogistic regimen. If there should be fixed pain of the chest, with any hardness of the pulse, a little blood may be taken from the arm, or topically, followed by a blister; the bowels must be kept regular, and diaphoretics employed, with demulcents and mild opiates, to quiet the cough. When the disease hangs about the patient in a chronic form, gentle tonics and expectorants are required, as myrrh, squill, &c. In the epidemic catarrh, more active evacuations are often required, the lungs being more seriously affected; but, though these should be promptly employed, they must not be carried too far, the disease being apt to assume the typhoid character in its progress; and, as the chief danger appears to be that suffocation may happen from the cause above mentioned, it is especially important to promote expectoration, first by antimonials, afterwards by squill, the inhalation of steam, &c., not neglecting to support the strength of the patient as the disease advances.

CATECHU; a brown astringent substance, formerly known by the name of *terra Japonica*, because supposed to be a kind of earth. It is, however, a vegetable substance, obtained from two plants; viz., the *mimosa*, or more correctly the *acacia catechu*, and the *ungaria gambir*. The first of these is a tree of from 20 to 30 feet high, found in abundance in many of the forests of India, from 16° of lat. up to 30°. The places most remarkable for its production, are

the Burman territories, a large province on the Malabar coast, called the Concan; and the forests skirting the northern part of Bengal, under the hills which divide it from Nepaul. The catechu is obtained from this tree by the simple process of boiling the heart of the wood for a few hours, when it assumes the look and consistency of tar. The substance hardens by cooling; is formed into small balls or squares; and being dried in the sun, is fit for the market. The price to the first purchaser in the Concan, is about 15*s.* a cwt. According to Dr. Davy, who analyzed it, the specific gravity of Concan catechu is 1.39; and that of Pegu 1.28. The taste of this substance is astringent, leaving behind a sensation of sweetness; it is almost wholly soluble in water. Of all the astringent substances we know, catechu appears to contain the largest portion of tannin. According to Mr. Rorkis, 1lb. is equivalent to 7 or 8lb. of our bark for tanning leather. From 200 grains of Concan concha, Dr. Davy procured 109 of tannin, 68 of extractive matter, 13 of mucilage, and 10 of earths and other impurities. The same quantity of Pegu catechu afforded 97 grains of tannin, 73 of extract, 16 of mucilage, and 14 of impurities. The uncaria gambir is a scandent shrub, extensively cultivated in all the countries lying on both sides of the straits of Malacca; but chiefly in the small islands at their eastern extremity. The catechu is in this case obtained by boiling the leaves, and inspissating the juice; a small quantity of crude sago being added to give the mass consistency; it is then dried in the sun, and being cut like the Concan catechu into small squares, is ready for use. There is a great consumption of this article throughout all parts of India, as a masticatory; it forms an ingredient in the compound of betel-pepper, areca-nut, and lime, which is in almost universal use. Catechu may be purchased at the Dutch settlement of Rhio, or at Malacca, in the straits of Singapore, at the rate of about 10*s.* a cwt. The quantity of it under the corrupted name of cutch, imported yearly into Calcutta from Pegu, at an average, at the five years ending with 1828-29, was about 300 tons, at a cost not exceeding 9*s.* per cwt. From Bombay a considerable quantity is annually imported into China. The quantity of catechu, under the name of gambir, produced in Rhio by the Chinese settlers, is equal to about 4,600 tons a year, about 2,000 of which are exported for the consumption of Java, the rest being sent to China, Cochin-China, and other neighbouring countries.

Catgut. The strings of certain musical instruments, the cords of clock-weights, and those of some other machines and implements, are made of a dense strong animal substance, denominated *catgut.* It is made from the intestines of different quadrupeds, particularly those of cattle and sheep. The manufacture is chiefly carried on in Italy and France. The texture from which it is made is that which anatomists call the *muscular coat,* which is carefully separated from the peritoneal and mucous membranes. After a tedious and troublesome process of steeping, scouring, fermenting, inflating, &c., the material is twisted, rubbed with horse-hair cords, fumigated with burning sulphur, to improve its colour, and dried. Cords of different size and strength, and delicacy, are obtained from different domestic animals. The intestine is sometimes cut into uniform strips, with an instrument made for the purpose. To prevent offensive effluvia during the process, and to get rid of the oily matter, the French make use of an alkaline liquid called *eau de Javelle.* Catgut for stringed instruments, as violins and harps, is made principally in Rome and Naples. For the smallest violin strings, three thicknesses are used; for the largest seven; and for the largest bass-viol strings, 120. In the kingdom of Naples, whence the best strings, commonly called *Roman,* are obtained, there are large manufactories of this article.

Cat-Harpings; small ropes in a ship, running in little blocks from one side of the shrouds to the other, near the deck. Their use is to force the main shrouds tight, for the ease and safety of the masts when the ship rolls.

Catoptrics; the science which treats of reflected light. It is a very important branch of optics, and will require particular notice. To render the subject intelligible, it will be necessary to take a brief view of the nature of reflecting bodies.

Any substance of a regular form, employed for the purpose of reflecting light, or of forming images of objects, is called a *speculum* or *mirror.* It is generally made of metal or glass, having a highly polished surface. The name of mirror is commonly given to reflectors that are made of glass; and the glass is always quicksilvered on the back, to make it reflect more light. The word *speculum* is used to describe a reflector which is metallic, such as those made of silver, steel, or of grain-tin mixed with copper.

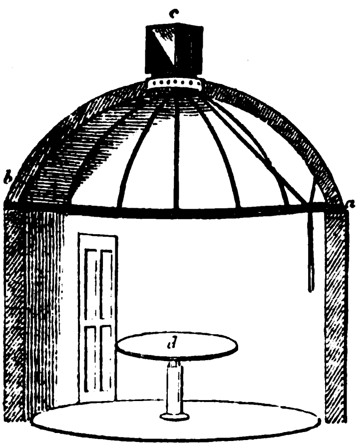
Specula or mirrors, are either *plane, concave,* o *convex.*

A *plane speculum* is one which is perfectly flat, like a looking-glass; a *concave speculum* is one which is hollow, like the inside of a watch-glass; and a *convex speculum* is one which is round, like the outside of a watch-glass.

As the light which falls upon glass mirrors is intercepted by the glass before it is reflected from the quicksilvered surface, we shall suppose all our mirrors to be formed of polished metal, as they are in almost all optical instruments. The image of any object is a picture of it formed either in the air, or in the bottom of the eye, or upon a white ground, such as a sheet of paper. Images are generally formed by mirrors or lenses, and accurately resemble the object in shape and colour; though they may be formed also by placing a screen, with a small aperture, between the object and the sheet of paper which is to receive the image.

Having thus illustrated the principal phenomena of reflection, we may now take two examples of its practical application in catoptrical instruments. The camera obscura, or dark chamber, is the name of an amusing and useful optical instrument, invented by the celebrated Baptista Porta. In its original state, it is nothing more than a dark room with an opening in the window-shutter, in which is placed a convex lens of one or more feet focal length. If a sheet of white paper is held perpendicularly behind the lens, and passing through its focus, there will be painted upon it an accurate picture of all the objects seen from the window, in which the trees and clouds will appear to move in the wind, and all living objects to display the same movements and gestures which they exhibit to the eye. The perfect resemblance of this picture to nature astonishes and delights every person, however often they may have seen it. The

image is of course inverted, but if we look over the top of the paper, it will be seen as if it were erect. The ground, *d*, on which the picture is received should be hollow, and part of a sphere whose radius is the focal distance of the convex lens. It is customary, therefore, to make it of the whitest plaster of Paris, with as smooth and accurate a surface as possible. In order to exhibit the picture to several spectators at once, and to enable any person to copy it, it is desirable that the image should be formed upon a horizontal table. This may be done by means of a metallic mirror, *c*, placed at an angle of 45°, the top revolving at *a b*, which will reflect the picture upon the white ground lying horizontally; an example of this kind, of the most improved construction, is given in the accompanying diagram.



In the more simple form of the instrument it is reflected upwards by the mirror, and received on the lower side of a plate of ground glass, with its rough side uppermost, upon which the picture may be copied with a fine sharp-pointed pencil.

All objects seen by reflection in a cylindrical mirror are necessarily distorted. If an observer looks into such a mirror, with its axis standing vertically, he will see the image of his head of the same length as the original, because the surface of the mirror is a straight line in a vertical direction. The breadth of the face will be greatly contracted in a horizontal direction, because the surface is very convex in that direction, and in intermediate directions, the head

will have intermediate breadths. If the axis of the mirror be held horizontally, the face will be as broad as life, but exceedingly short. If a picture or portrait, *c d*, is laid down before a mirror, *a b*, the reflected image will be highly distorted; but the picture may be drawn distorted according to regular laws, so that its image shall have the most correct proportions.

Cylindrical mirrors, similar to that represented above, which are now very uncommon, used to be made use of for this purpose, and were accompanied with a series of distorted figures, which, when seen by the eye, have neither shape nor meaning, but when laid down before a cylindrical mirror, the reflected image of them has the most perfect proportions.

CAT'S-EYE. See ASTERIA and QUARTZ.

CATSUP. See KETCHUP.

CAULKING, or CAUKING, of a ship, consists in driving a quantity of oakum, or old ropes untwisted and drawn asunder, into the seams of the planks, or into the intervals where the planks are joined together in the ship's decks or sides, in order to prevent the entrance of water. After the oakum is driven very hard into these seams, it is covered with hot melted pitch or resin, to keep the water from rotting it. Among the ancients, the first who made use of caulking were the inhabitants of Phœnicia, now Corfu. Wax and resin appear to have been commonly used previously to that period. The Poles use a sort of unctuous clay for the same purpose on their navigable rivers.

CAUSTIC. The name of *caustic* is given to substances which by their chemical action disorganize the parts of the body with which they are put in contact. They are called, likewise, *potential cauteries*, to distinguish them from the fire called *actual cautery*. Caustics, in general, act by decomposing chemically the tissues to which they are applied, by depriving them of life, and producing a real, local, and circumscribed gangrene, called *eschar*, or *slough*. Those, the action of which is powerful—for instance, caustic potassa, concentrated sulphuric acid, &c.—produce these phenomena with such rapidity that inflammation takes place only after the formation of the *eschar;* whilst, on the contrary, inflammation is the immediate consequence of the less energetic caustics. In both cases suppuration occurs sooner or later, and separates the disorganized from the surrounding parts. Almost all the substances used as caustics have only a local action: some, however, are capable of being absorbed, and of exercising a deleterious action on the economy in general: arsenical preparations are an instance of it.

The employment of caustics is now confined to a small number of cases. The actual cautery and the knife are in general preferred to them. They are used principally in order to establish issues, particularly in cases in which it is necessary to produce a powerful derivation; to stop the progress of certain gangrenous affections, such as *anthrax;* to open certain indolent abcesses; to change the mode of vitality of the skin in some cancerous or herpetic ulcers; to destroy the excrescences of wounds or proud flesh; and, finally, to prevent the absorption of the virus deposited at the surface of poisoned wounds.

CAUSTIC POTASSA; impure hydrate of protoxide of potassium; caustic kali with lime; common caustic. This is seen in flat, irregular, brittle pieces, or in round sticks, like the nitrate of silver; of a grayish-white, sometimes reddish; of a savour extremely caustic, and a slight odour *sui generis*. This substance is extremely caustic; it decomposes quickly the parts

with which it is put in contact, and leaves on the skin a soft, grayish, *eschar*, which comes off slowly. Taken internally, it acts in the same way as all corrosive poisons; it has nevertheless been administered in very dilute solutions, as an antacid, diuretic, and lithontriptic. It has succeeded in the gravel, in nephritic colics, and other affections proceeding from superabundance of uric acid. It has been recommended, likewise, in the treatment of scrofula, and in some diseases of the skin, such as leprosy, &c.—This solution, even when very diluted, soon irritates the stomach, and brings on anorexia, which prevents it from being used for any length of time.

Caustic Soda; protoxide of sodium. Its physical properties are similar to those of potassa, and it may be used with advantage as a *succedaneum* when employed as a caustic. In fact, the sub-carbonate, which forms during its action on the skin, is not deliquescent, as that of potassa, and consequently is not subject to spread.

Cavalier, in fortification, is a work generally raised within the body of the place, 10 or 12 feet higher than the rest of the works. It is most commonly situated within the bastion, and made much in the same form. Sometimes the cavaliers are placed in the gorges, or on the middle of the curtain; they are then made in the form of a horse-shoe. Their use is to command all the adjacent works and surrounding country. They are seldom made except when a rising ground overlooks some of the works. In modern times it is considered that cavaliers in a bastion occupy too much room, render retrenchments impossible, and unless a ditch separates the cavalier from the parapet of the bastion, cause the grenades to fall upon the defenders of the latter; for which reasons it is considered best to put them on the curtains or behind the bastions.

Cavalry; one of the three great classes of troops, and a formidable power in the hands of a leader who knows how to employ it with effect. This requires a bold and active spirit, able to avail itself with quickness and decision of every opportunity. The efficacy of cavalry arises particularly from the moral impression which it produces on the enemy. This is greater in proportion to the size of the mass and the rapidity of its motion. Its adaptation to speedy movements is another great advantage, which enables a commander to avail himself immediately of a decisive moment when the enemy exposes a weak point, or when disorder appears in his ranks. It is a very important instrument in completing the defeat of an enemy, in disconcerting him by a sudden attack, or overthrowing him by a powerful shock. The use of cavalry is, it is true, oftentimes limited by the nature of the ground. In forests, in mountainous districts, on a marshy soil, &c., it is of but little avail in large bodies. In modern times cavalry has been led against entrenchments, but only to its own destruction. In some instances, too, the cavalry has been dismounted, and employed as infantry; which may on peculiar occasions be advisable, but, on the whole, is contrary to their nature and purpose, and if made a part of their duty, like other half measures, is usually disadvantageous. It is also unadvisable to keep large bodies of cavalry united during a campaign. They are to be collected in large masses only for particular objects. To keep them together the whole time would be troublesome, and their maintenance frequently attended with difficulty.

The unequal size of the horse, the very great diversity in his strength and breed, have at all times rendered it necessary to divide the cavalry into *light* and *heavy horse*. There is sometimes, also, an intermediate class. These different sorts are employed for different purposes. The heavy cavalry with defensive armour (cuirassiers), is more frequently employed in mass, where force is requisite; the lighter troops are used singly, and in small detachments, where swiftness and continued effort are required. Nevertheless, cuirassiers and dragoons, lancers and hussars, mounted riflemen and *chevaux legers*, must, in the main points, be equally exercised in the duties appertaining to cavalry, and must be able to fight in the line as well as singly. The use of cavalry is probably nearly as ancient as war itself; for in those countries where horses thrive most, and man may be said to live on horseback, he has always preferred to fight on horseback.

The Egyptians are said to have had cavalry before the time of Moses. The Israelites, when at war with their neighbours, often had to encounter cavalry, but were afraid to mount horses until the time of Solomon. The Greeks appear not to have introduced cavalry into their armies till the second Messenian war, and even after that time had comparatively few; but with them it was considered the most respectable class of troops, in which only the wealthy citizens served. The Persian cavalry, and at a later period the Macedonian, were much more numerous. The Romans learnt its use from Pyrrhus and the Carthaginians. At a later period the cavalry of the Gauls was particularly good. In the middle ages, the knights fought only on horseback, and disdained the foot-service. At this period, however, regular warfare was unknown, and was only gradually restored in the progress of time. After the introduction of artillery, although cavalry was used, yet its manoeuvres were awkward and inefficient. The genius of Gustavus Adolphus first perceived the important use which could be made of it. He was without the heavy cavalry, which, since the time of chivalry, had gone out of use; but he found that the advantage of this species of troops did not consist in its weight, but in its quickness of motion. With reference to this, he formed his regiments of horse, and showed their real utility; but it was left to Seidlitz, a general of Frederic the Great, to display this most fully. Napoleon appears to have been well aware of the great value of cavalry in large masses, but he often sacrificed them unsparingly. This, together with certain erroneous dispositions which had crept into some armies, and had caused the cavalry to fail in services on which they ought never to have been put, and which were sometimes performed as well or better by other troops, gave rise, of late years, to doubts concerning their utility, which, however, are now abandoned. *(Statements and Observations respecting the Conduct and Fate of the Cavalry in the Campaigns of Frederic II., and in those of a later Period.)* In the north of Europe, lances are now common among the light cavalry, as they have proved a formidable weapon when skilfully used. They will no doubt, effect a change in the arms, and even in the organization of the infantry, who can do little against lancers, if rain prevents them from firing. In the Prussian cavalry, which is among the finest in the world, lancers are very numerous. A French author calls the cavalry, very appropriately, *l'arme du mo-*

ment; because they are peculiarly fitted to take advantage of decisive moments. A moment may occur, when a great victory can be decided by the sudden irruption of a body of cavalry, and the next moment it may be too late. A commander of cavalry must therefore be possessed of the rare courage which shrinks not from responsibility. Many battles in the late wars prove the truth of these remarks. Napoleon won the battle of Marengo chiefly by Kellermann's daring charge, at the head of 500 horse, on an enemy almost sure of victory. The campaigns in Russia, and the following war in Germany, showed the great disadvantage under which an army labours from the want of cavalry. Napoleon failed to follow up his advantages after the victories of Lützen and Dresden, chiefly because his cavalry were raw and inexperienced. The training of cavalry is much slower than that of infantry. The best cavalry is now generally considered to be the Prussian, and some species of the British. The French never were good horsemen, and the English have hardly kept pace with the numerous improvements introduced by the wars on the continent. It is a fact of interest, that the more civilization takes root among a nation, the more importance is given to infantry. All savage nations begin with cavalry, if they have horses. At present, infantry is the most numerous class of troops, though before the time of Charles V. they were little esteemed.

Caviare; the spawn or roe of sturgeon: it is either salted, dried, and made into small cakes, or is in its natural state packed up in kegs. It is in great repute in Russia, on account of the three seasons of Lent in that country. The sturgeon is found in the mouth of most of the rivers of Russia, particularly those which fall into the Caspian Sea. The sturgeon at the mouth of the Wolga, near Astrachan, is of a very large size.

Cavatina; a short air without a return or second part, and which is sometimes relieved with recitative.

Cayenne Pepper, or Capsicum. All the species of capsicum possess the same general qualities. In hot climates, but particularly in the East and West Indies, and some parts of Spanish America, the fruit of these plants is much used for culinary purposes. It is eaten in large quantities, both with animal and vegetable food, and is mixed in greater or less proportion with almost all kinds of sauces. The Cayenne pepper used in cookery is made from the fruit of different species of capsicum. This fruit, when ripe, is gathered, dried in the sun, and then pounded; and the powder is mixed with a certain portion of salt, and kept for use in closely-stopped bottles. It is very generally used as a poignant ingredient in soups and highly-seasoned dishes. Its taste is extremely acrid, and it leaves a durable sensation of heat on the palate, which is best removed by butter or oil. When taken in small quantities, Cayenne pepper is a grateful stimulant; and in medicine it is used both externally and internally, to promote the action of the bodily organs, when languid and torpid; and it is said to have been found efficacious in many gouty and paralytic cases. The Guinea pepper, or annual capsicum, is considered the most hardy of this whole tribe of plants; and in many parts of the south of Europe its fruit is eaten green by the peasants at their breakfasts, and is preferred by them to onions or garlic. The fruit of all the species may be used in domestic economy, either as a pickle, or when dried before a fire and ground to powder in a common pepper-mill, as Cayenne pepper.

Cell. This term is employed very frequently to signify any small compartment into which substances are divided; thus the hexagonal chambers of the honeycomb are called *cells*, as in botany the cavities separated by partitions in the pods, husks, or seed-vessels of plants, which are said to be *unilocular, bilocular, trilocular*, &c., according to the number of cells.

In anatomy, it is applied to various small cavities, such as the air-cells, or pulmonary vesicles, the adipose cells, or spaces in the membrane which retains the fat, &c. The loose, inflatable texture which unites and surrounds all the parts and organs of the body, has the name of *cellular*, from its being made up of a succession of these little interstices.

Cellular Substance, or Cellular Membrane (*tela cellulosa* or *mucosa* of Latin writers), is the medium which connects and supports all the various parts and structures of the body. Any person may gain a general notion of this substance by observing it in joints of veal, when it is inflated by the butchers. It consists of an assemblage of fibres and *laminæ* of animal matter, connected with each other so as to form innumerable cells or small cavities, from which its name of *cellular* is derived. It pervades every part of the animal structure. By joining together the minute fibrils of muscle, tendon, or nerve, it forms obvious and visible fibres. It collects these fibres into large *fasciculi*, and by joining such *fasciculi*, or bundles, to each other, constitutes an entire muscle, tendon, or nerve. It joins together the individual muscles, and is collected in their intervals. It surrounds each vessel and nerve in the body, often connecting these parts together by a firm kind of capsule, and in a looser form, joining them to the neighbouring muscles, &c. When condensed into a firm and compact structure, it constitutes the various membranes of the body, which, by long maceration in water, may be resolved into a loose cellular texture. In the bones it forms the basis or groundwork of their fabric, a receptacle, in the instertices of which the earth of bone is deposited.

As cellular substance is entirely soluble in boiling water, it is considered by chemists as that peculiar modification of animal matter termed *gelatine*. In consequence of its solution by the united agencies of heat and moisture, the muscular fibres separate from each other, and form the other structures of the body. This effect is seen in meat which is subjected to long boiling or stewing for the table, or, indeed, in a joint which is merely over-boiled. It forms a connection and passage between all parts of the body, however remote in situation or dissimilar in structure; for the cells of this substance every where communicate, as we may collect from facts of the most common and familiar occurrence. In emphysema, where air escapes from the lungs wounded by a broken rib into the cellular substance, it spreads rapidly from the chest into the most remote parts of the body, and has even been known to gain admission into the eye-ball. A similar diffusion of this fluid may be effected by artificial inflation.

Cements. The substances used for producing cohesion between different materials are very various. They are mostly, however, soft or semi-fluid, and harden in the course of time. The number employed is very great. We can mention only a few. The

joints of iron pipes, and the flanges of steam-engines, are cemented with a mixture composed of sulphur and muriate of ammonia, together with a large quantity of iron chippings. The putty of glaziers is a mixture of linseed oil and powdered chalk. Plaster of Paris, dried by heat, and mixed with water, or with rosin and wax, is used for uniting pieces of marble. A cement composed of brick-dust and rosin, or pitch, is employed by turners, and some other mechanics, to confine the material on which they are working. Common paint, made of white lead and oil, is used to cement China-ware. So also are resinous substances, such as mastic and shell lac, or isinglass dissolved in proof spirit or water. The paste of bookbinders and paper-hangers is made by boiling flour.

Rice-glue is made by boiling ground rice in soft water to the consistence of a thin jelly. Wafers are made of flour, isinglass, yeast, and white of eggs, dried in thin layers upon tin plates, and cut by a circular instrument. They are coloured by red-lead, &c.

Sealing-wax is composed of shell lac and rosin, and is commonly coloured with vermilion. Common glue is most usually employed for uniting wood, and similar porous substances. It does not answer for surfaces not porous, such as those of the metals, and is not durable if exposed to water.

The cements mostly used in building are composed of lime and sand. Lime is procured by burning substances in which it exists in combination with carbonic acid, such as limestone, marbles, chalk, and shells. By this process, the carbonic acid is driven off, and quicklime is obtained. The quicklime is slaked by mixture with water, after which it swells and cracks, becomes hot, and assumes the form of a white and impalpable powder. This is a hydrate of lime, and contains about three parts of lime to one of water. When intended for mortar, it should be immediately mixed with sand, and used without delay, before it imbibes carbonic acid anew from the atmosphere. The lime adheres to and unites the particles of the sand. Cements thus made increase in strength and solidity for an indefinite period. Fresh sand, wholly silicious and sharp, is the best. That taken from the sea-shore is unfit for making mortar, as the salt is apt to deliquesce and weaken the mortar. The amount of sand is always greater than that of the lime. From two to four parts of sand are used, according to the quality of the lime and the labour bestowed on it.

Water cements, called also *Roman cements*, harden under water, and consolidate almost immediately on being mixed. Common mortar dissolves or crumbles away, if laid under water before it has had time to harden; but certain rocks, which have an argillaceous as well as a silicious character, communicate to lime or mortar the property of hardening in a very few minutes, both in an out of water. The ancient Romans, in making their water cements, employed a peculiar earth, obtained at the town of Puteoli. This they called *pulvis Puteolanus*. It is the same that is now called *Puzzolana*. It is evidently of volcanic origin. The Dutch, in their great aquatic structures, have mostly employed a substance denominated *tarras, terras*, or *trass*, found near Andernach, in the vicinity of the Rhine. It is said to be a kind of decomposed basalt, but resembles Puzzolana. It is very durable in water, but inferior to the other kinds in the open air. Baked clay and the common greenstone afford the basis of very tolerable water cements, when mixed with lime. Some of the ores of manganese may be used for the same purpose. Some limestones, calcined and mixed with sand and water, also afford water cements, usually in consequence of containing some argillaceous earth.

Some cements, of great hardness and permanency, have been obtained from mixtures into which animal and vegetable substances enter, such as oil, milk, mucilage, &c. The name of *maltha* or *mastic* is given them. They are not much used.

The cement or plaster commonly used in France (which consists of a mixture of chalk, and strong size), is objectionable as being deficient in hardness, apt to chip or scale off, and unable to resist the rain. An ingenious experimentalist states, that a composition formed of slaked lime, mixed with 4 to 5-100 parts of alum, though dearer than the former, has been found preferable on account of its adhering more firmly to the wall, and better calculated to resist the inclemencies of the weather, which he conceives is owing to the alumine of the alum becoming incorporated with the lime. Following the advice of M. Dulong, he has endeavoured to imitate this cement on a more economical principle. To effect this, he has diluted slaked lime and white clay with water, and after mixing, suffered them to blend together and re-act upon each other for some time at an ordinary degree of temperature. The proportions of the separate ingredients are 100 parts of quicklime, five of white clay, and two of yellow-ochre. The process is as follows:

The lime is first slaked with a small quantity of water, more of which is added by degrees until the mixture is reduced to about the consistency of cream; the white clay is also diluted, and brought to a similar state, by being suffered to remain for some time in water, and the two solutions are then mixed carefully together.

The parts of walls covered with this cement, which have been exposed in the country, to the influence of the south-west winds, and rain, for the space of two years, have lost none of their colour, nor can any portion of the plaster be rubbed off by the hands.

Cementation; a chemical process, in which a metal (and often other bodies) is placed in connection with other substances, often in layers, in close vessels, that the former may be separated from its combinations, or changed (frequently oxydated), at a high temperature. The substance with which the metal or other body is surrounded is called *cement-powder*. In cementing gold, the alloy is beaten into thin plates, and placed in alternate layers, with a cement containing nitrate of potass and sulphate of iron. The whole is then exposed to heat until a great part of the alloying metals are removed by the action of the nitric acid liberated by the nitre. Iron is cemented with charcoal-powder and other substances, and thereby converted into steel. Glass is changed by cementation with gypsum, into Réaumur's porcelain. Copper is cemented with a powder of calamine and charcoal, and thereby converted into brass. The copper obtained from the sulphate of copper, by precipitation with iron, is called *cement copper*.

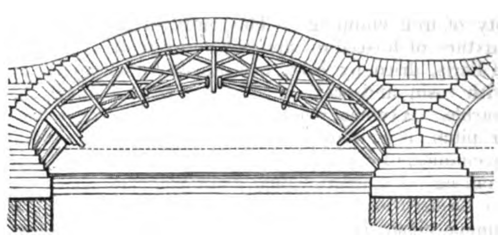
Cenotaph; a monument erected in honour of a deceased person, but not containing his body. Some of these monuments were erected in honour of per-

sons buried elsewhere, others for persons whose bodies were not interred. The ancients believe that, when the body was not buried, the soul could not be admitted into the abodes of the blessed. When a body could not be found, it was supposed that some rest was afforded to the sufferer by erecting him a cenotaph, and calling out his name three times with a loud voice. Such monuments were distinguished by a particular sign, usually a piece of a shipwrecked vessel, to denote the death of the deceased in a foreign land. The Pythagoreans erected cenotaphs to those who had quitted their sect, as if they were actually dead. We subjoin an example of a beautiful modern cenotaph, combining the purest principles of Greek sculpture with the most simple architectural adornments.

Centaur; a part of one of the old constellations. In Ptolemy's Catalogue the stars are 37 in number; and in the Britannic Catalogue 35. For an account of the comparative lustre of some of the stars in this combined constellation by Dr. Herschel, see the *Philosophical Transactions* for 1797, p. 314.

Centaury. There exist two plants of this name, used in medicine; *small centaury* and *American centaury*, extensively distributed throughout the United States. Both are esteemed as tonics and febrifuges: the latter, however, is preferred by the American physicians. It is also much used in domestic practice as a prophylactic against autumnal fevers, in strong infusions, in large and repeated doses.

Centering; in bridge building. A person unacquainted with the process by which the large curved vaults of masonry are erected for the arches of a bridge, might suppose some very complete mass of frame-work was required for the purpose; such however is not the case, as the centering merely consists of a series of timbers supported in the air, precisely in the same way as the stone-work is afterwards arranged. We give a view of the mode of effecting this in an arch of the largest span.



The first step in building a bridge is to prepare a coffer-dam, or water-tight chamber, by driving piles in the bed of the stream, and having pumped out the water from within, the piers are erected. If we now suppose them to be raised above the water line, the process of "centering" commences. The frame-work of which it is composed is elevated by a pair of high *shears*, like those used for placing a mast of a vessel in its seat. The arrangement of the bars in the centre will be readily seen by a reference to the figure; but the way by which it is afterwards removed will require a more particular notice.

It should be borne in mind, that when the arch is completed, it presses with enormous force on the wooden frame—with a force, indeed, equal to that of many hundred tons. Now to get over this apparently insurmountable difficulty in the way of their removal, the base of each line of timbers rests on a series of wedges, so that every blow of the hammer applied to the point of the wedge, tends to facilitate the removal of the centre, and in this way the enormous masses of stone, forming the arches of London Bridge, were brought into a state of equilibrium in mid-air, and afterwards left to support their own giant frame-work.

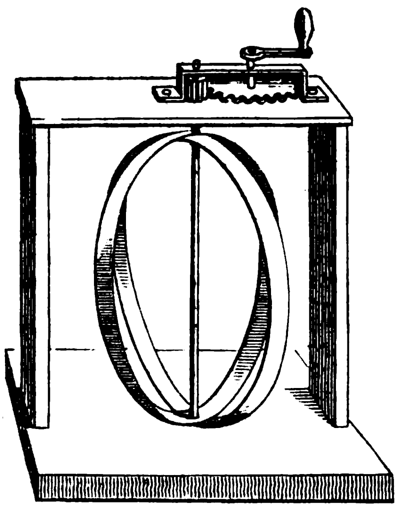
Centiare; a French measure, the hundredth part of an *are;* thus, also, according to the new French division of measures and weights, we have *centigramme, centilitre, centime, centimetre,* the hundredth part of a *gramme, litre, franc, metre.*

Central Fire. Many natural philosophers have supposed a perpetual fire to exist in the centre of the earth, which they call *central fire.* In ancient times, volcanoes and other similar phenomena were explained by it. At a later period, when it was understood that such a fire in the interior of the earth was impossible, the phrase was used to express the interior warmth of the earth. To this central warmth Mairan ascribes a great part of the warmth on the surface of the earth. To a certain depth there appears to be a fixed temperature in the interior of the earth, which probably arises from the penetrating heat of the sun. At least experiments show that in hot climates the interior of the earth is warmer than in cold ones. In Siberia, for instance, some workmen having penetrated 80 feet in digging a well, found the earth frozen even at that depth. Interesting information on this subject may be found in Biot's *Astronomie Physique.*

Central Forces; those forces by the co-operation of which circular motion is produced; that is, the centripetal and centrifugal forces. Many natural philosophers deny the existence of the latter, and assert it to be a mere mathematical idea. They say, a body once put in motion, continues its motion in the same direction, and with the same velocity, with-

out the interposition of a new power, on account of its *inertia*. Now, the heavenly bodies were impelled in the beginning by the Creator, with an almighty power, and would be obliged, by their *inertia*, to go on eternally in one direction, and with the same velocity, if they were not attracted, in all points of their motion, towards a point out of this direction, by which a circular motion is produced. Of the first moving force, there is now no longer any question. That power by which the heavenly bodies are drawn towards points out of their rectilinear path, is called the *centripetal force*. This power would put the heavenly body in motion if it were at rest; as it finds it already in motion, it changes its direction at every point. The case is quite different with the *centrifugal force*. This appears to be merely the result of the *inertia* of the body, or rather of the motion which, having been once given to the body, is continued by means of this *inertia*.

CENTRIFUGAL FORCE, in *Physics*, is the result of motion in any body made to revolve in a circle, which produces a tendency in the body to fly off from the centre of motion. One of the simplest modes of illustrating this effect, is to put water in a bucket, and if the experimentor whirl it round by a cord attached to the handle, no portion of the water will be spilt. The centrifugal force overcomes the gravitating force, and the fluid remains in the bucket.



A still more beautiful illustration may be given with the instrument represented above. Two elastic hoops being placed on one axis, are made to revolve by a multiplying wheel and handle, and as soon as motion is communicated they assume the form of an oblate spheroid. They expand at their equator, and are depressed at their poles. We give a figure of the instrument as it is found in the apparatus room of the London Institution, but by substituting a band for the toothed wheels, a more quiet and equable motion is produced.

Another mode of showing the same fact will be given under our article WHIRLING-TABLE, which is an instrument of considerable importance in central forces.

CENTRIPETAL FORCE. See CENTRAL FORCES.

CENTRO-LINEAD. See VANISHING POINT.

CENTURY (Latin *centuria*); a division of 100 men. This kind of division was very common with the Romans, and was used in general to denote a particular body, although this might not contain exactly 100 men. Thus, centuries in the army were the companies into which the Roman legions were divided.

CEPHALIC VEIN; one of the large superficial veins of the upper extremity.

CEPHEUS, in *Astronomy;* a constellation of the northern hemisphere, being one of the forty-eight old asterisms.

CERATE, in the materia medica; a kind of stiff unguent or liniment, made of oil and wax, with other ingredients; used externally in several diseases, especially those of the skin.

CERBERUS; a small northern constellation near Hercules.

CEREBELLUM, in *Anatomy;* that portion of the contents of the cranium which is contained in the lower fossæ of the occipital bone, and covered by the tentorium.

CEREBRUM, in *Anatomy*. This term in common language denotes the brain in general; but anatomists confine it to that part of the encephalon which occupies all the upper part of the cranium; indeed, by far the largest portion of the cavity.

CERES, in *Astronomy;* a new primary planet, discovered on the 1st of January, 1801, by the celebrated astronomer Piazzi. For a farther account of this planet, see ASTRONOMY.

CERINTHUS. See GNOSTICS and MILLENNIUM.

CERIUM, a rare metal, was discovered in 1803, by MM. Hisinger and Berzelius, in a Swedish mineral, known by the name of *cerite*. Dr. Thomson has since found it, to the extent of 34 per cent., in a mineral from Greenland, called *allanite*. The properties of cerium are in a great measure unknown. It is a brittle, white metal, which resists the action of nitric, but is dissolved by nitro-muriatic acid.

CERUSE, or white-lead, is an oxide of lead, saturated with carbonic acid, and is prepared as an article of commerce, by the action of acetic acid on the metal. Plates of lead being exposed to the vapours arising from boiling vinegar, are oxydised by the action of the air and the affinity of the acid. To obtain it in large quantities, plates of lead about 3 feet long, 6 inches broad, and 1 line thick, are rolled up in such a manner, that a space of half an inch or an inch is left between each roll. These rolls are fixed perpendicularly in earthen vessels which at the bottom contain strong vinegar. The latter, however, must not touch the plates; and, to prevent this, some little bars are placed over it in the form of a cross. The vessels are then covered with plates of lead, and being placed horizontally in tan or horse-dung, are exposed to a gentle heat. The vinegar now rises in vapours, which settle on the surfaces of the lead plates, penetrate them, and dissolve a great portion of the metal. In the space of from 3 to 6 weeks, the vapours of the acetic acid become saturated with lead, and change the latter into a whitish substance, which after some time is scraped off the plates, unrolled for this purpose. The plates are then rolled up again, and the same process is repeated. Ceruse is extensively used in the manufacture of oil paints, and, for this purpose, it is reduced to a fine powder. The pounding and bruising, however, are extremely injurious to the health.

The dust, if swallowed, causes a dangerous disease called the *painters' colic.*

CETUS, in *Astronomy* (the *Whale*); a large constellation of the southern hemisphere (being one of the forty-eight old asterisms) under Pisces, and next to Aquarius.

CHAIN, in surveying, is a measure consisting of a certain number of links of iron wire, serving to take the dimensions of fields, &c.

Chain, in nautical language. Chains are strong links or plates of iron, the lower ends of which are bolted through a ship's side to the timbers. They are also on the outside, and are used to contain the blocks called *dead-eyes,* by which the shrouds of the masts are extended. *Top chains* are those which preserve the lower yards from falling, when, in time of battle, the ropes are rendered incapable of service. Chains are now employed to a great extent for rigging.

CHAIN, GEARING. An ingenious and useful construction of gearing chain for connecting cog-wheels, has lately been invented by Mr. Oldham, engineer, of the Bank of Ireland, which we think highly deserving of the attention of machinists, as it is so extensively applicable to various kinds of machinery, such as carding engines; and indeed in almost every situation where a series of toothed wheels are required to be driven by one mover. It consists of a peculiarly constructed chain, with curved links, which when passed round a drum will serve as teeth, and act as a cog-wheel to turn pinions, &c.; and when stretched out straight, or placed on a flat surface, will form an endless rack. It may also be passed over and under a series of rollers, pinions, &c., forming a carrying-chain instead of the commonly constructed chains, in which spiked wheels are employed to take in the links.

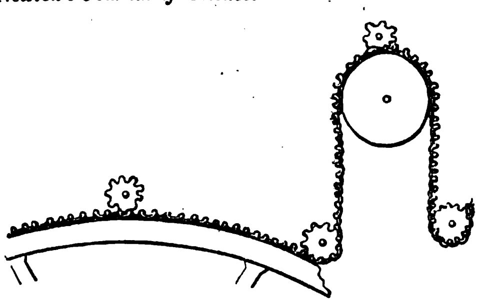
In carding engines, and various other kinds of machinery, this improved chain will work with much better effect in connection with pinions, or wheels with common teeth, into which it is suited to gear, than the old chains, and without the possibility of slipping off, or riding over the points of spiked wheels; having a broader surface of contact: and it is not at all liable to get out of order, being much stronger than the old linked chain used with spur pinions.

It is formed by crescent-shaped plates constituting links, which are connected together; and one and two plates alternately, or two and three, or more placed side by side; the alternate links fitting in between each other at the joints, where they are connected by pins, or bolts passed through their eyes in lateral directions.

It will be obvious that these curved links present on one surface of the chain semi-circular hollows like a rack, for the teeth of the pinions to take into, and that the ends of the links, where the bolts or rivets are passed through, are also formed semi-cirular, and the same size as the spaces or hollows of the links. These ends constitute teeth on the chain, and take into the spaces between the teeth of the pinions or wheels, and consequently drive them; or the chain itself may be driven by such pinions or wheels in the same way as a rack.

It is evident that such a chain may be passed in various directions over wheels, on its face, and over drums at its back, and may be used with certainty of effect: as whatever motion is given to the chain, will be communicated to all that is in gear with it.

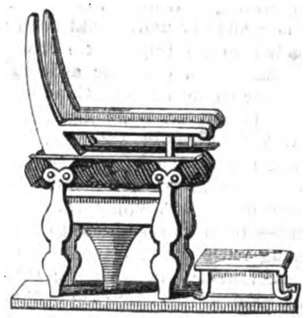
The accompanying engraving shows such a chain, supposed to be endless, carried over part of the periphery of a carding cylinder, and constituting a circular rack or toothed rim, which drives all the pinions connected to it; the back of the chain is conducted over a roller, and brought into gear with other pinions or wheels; but as numerous illustrations might be produced of its applicability, it is unnecessary to say more, as its adaptation to a very wide range of machinery will at once be perceived by every practical mechanic. For a farther account of this contrivance, and much useful information on similar subjects, see *Newton's Journal of Science.*



CHAIN-TIMBER; a timber of large dimensions, placed in the middle of a building, to give it strength.

CHAIR. The use of this valuable appendage to the domestic comfort of European nations is but little known in the warmer climates of the globe. Couches and mats are still employed over three-fourths of the earth.

The Etruscans were the first to use them generally, and yet strange to relate, the best form of our modern chairs scarcely exceeded those of Etrurian manufacture in point of beauty or convenience. An illustration of this fact will be found in the accompanying design, which is carefully copied from a bas-relief figure.



Etruria was at the height of its glory prior to the building of Rome, and yet the former people were more eminently skilled than their conquerors in all the arts which tend to the comfort and convenience of life. The chairs, as they are now constructed, are too well known to render any farther notice necessary; but our readers will find under the article BANQUET, in the SECOND DIVISION of this work, a graphic illustration of the species of couch formerly employed by the Romans, and still used in the East.

CHALK. See LIME.

CHAMADE, in military language (generally derived from the Italian *chiamare,* to call), is a signal, either by beat of drum or sound of trumpet, to obtain a

conference, when any matter is to be proposed to the enemy.

Chamber *of a Cannon*, in artillery; that part of the bore of a cannon which receives the powder with which it is charged.

Chamber of a mortar; the space where the powder lies.

Chamber of a mine; the place where the charge of powder is lodged that is to be used for blowing up the works.

Chamber of a battery; a place sunk under ground to hold the powder, bombs, &c., so as to preserve them from ruin or moisture.

Chamber of a lock is the space between the gates of a lock in a canal, in which the barge rises and sinks, so as to pass the lock. See Canal.

Chamomile, Roman; a perennial plant, native of Europe, and flowering in June or July. Chamomile flowers, such as they are found in the shops, are white, desiccated, of a very aromatic and rather pleasant smell, and of a very bitter and warm taste. They contain an essential oil of a fine blue colour, a gum-resinous principle, camphor, and tannin.—Water and alcohol dissolve their active principles. The Roman chamomile is a moderately energetic stimulant, possessing, on account of its bitterness, some tonic properties, which have rendered it a popular remedy for a number of diseases. It is employed with success to stimulate the digestive functions in dyspepsia, chlorosis, gout, in flatulent colics, &c. It is also advantageously used in slight intermittent fevers and spasmodic affections. A strong infusion, taken warm, and in a large quantity, provokes vomiting. The common chamomile is now out of use.

Champagne is a wine which is made chiefly in the department of the Marne, in the *ci-devant* province Champagne, and is commonly divided into river and mountain wines (*vins de la rivière de Marne*, and *vins de la montagne de Reims*); the former being, for the most part, white, the latter red. Not all of these wines are sparkling or frothing, though by the name *champagne* is generally understood such wine as has been subjected to an imperfect fermentation, and contains a quantity of carbonic acid gas, generated during the insensible fermentation in the bottle, which is disengaged on removing the pressure by which it was detained in solution. The briskest wines are not always the best; they are, of course, the most defective in true vinous quality; and the small portion of alcohol which they contain immediately escapes from the froth as it rises on the surface, carrying with it the aroma, and leaving the liquor that remains in the glass nearly vapid. For it has been shown, by Humboldt, that when the froth is collected under a bell-glass surrounded with ice, the alcohol becomes condensed on the sides of the vessel. Hence the still, or the creaming, or slightly sparkling Champagne wines (*vins crêmans*, or *demi-mousseux*) are more highly valued by connoisseurs, and fetch greater prices than the full-frothing wines (*vins grand mousseux*). By icing these wines before they are used, the tendency to effervesce is in some degree repressed; but when they are kept cool, this precaution is unnecessary. In general it may be observed, that the vineyards on the banks of the Marne supply the choicest wines, and that the quality degenerates in proportion as they recede from the river. Among the white wines of Champagne, the first rank is generally assigned to those of Sillery, the produce of the vineyards of Verzenay, Mailli, Raumont, &c. Of the Reims mountain wines, those of Verzi, Verzenay, Mailli, Bouzy, and St. Basle, are most esteemed; but the Clos St. Thierry furnishes perhaps the finest red champagne. The name *jolly champagne*, under which at present a large quantity of the best champagne is sold in the United States, does not originate from a place in Champagne, but from the owner of extensive vineyards in that province, who exports much champagne to the United States. The soil of the principal vineyards throughout Champagne is composed of a loose marl, resting on chalk, and sometimes mixed with flints. For the manufacture of the white champagne wines black grapes are now generally used. In making the red wines the grapes are trodden before they are introduced into the vat. Champagne, when well made, and placed in cool cellars, will retain its good qualities from 10 to 20 years. (For farther information respecting this delicious liquor, and the art of making it, see A. Henderson's *History of Ancient and Modern Wines*, London, 1824.

Champ-de-Bataille *(field of battle)*, in military language, is the ground on which an action is fought. The commander who obliges his adversary to quit this ground and abandon it to him, obtains the victory.

Chance is used to signify accident, and also probability. The latter is its meaning in mathematics. The doctrine of chances teaches how to find the probability of a given event taking place from an examination of the circumstances affecting it. It is called more properly by the French, *calcul des probabilités.* It is important for the calculation of insurance risks, the worth of life-annuities, &c. Pascal, Huygens, De Moivre, Parisot (*Traité du Calcul conjectural*, &c., Paris, 1810, 4to.), Laplace, Lacroix (*Traité élémentaire du Calcul des Probabilités*, Paris, 1816), and others, have written ably on this subject. James Bernouilli undertook a work *De Arte conjectandi*, but his death prevented its completion.

Chancel is that part of the choir of a church, between the altar or communion-table and the rail that encloses it, where the minister is placed at the celebration of the communion.

Channels, or Chain-Wales, of a ship; broad and thick planks projecting horizontally from the ship's outside, abreast of and somewhat behind the masts. They are formed to extend the shrouds from each other, and form the axis or middle line of the ship, so as to give greater security and support to the masts, as well as to prevent the shrouds from damaging the gunwale, or being injured by rubbing against it.

Chant. See Church Music.

Character. This name is given to certain marks used to signify objects or ideas. The ancient written language of the Chinese is a language of figures, every object or notion being expressed in it by a particular figure. We also, for the sake of brevity and precision, use in several sciences, certain signs: for instance—*Astronomical Signs:* ☉ Sun; ☽ Moon; ⊕ Earth; ☿ Mercury; ♀ Venus; ♂ Mars; ⚶ Vesta; ⚵ Juno; ⚴ Pallas; ⚳ Ceres; ♃ Jupiter; ♄ Saturn; ♅ Herschel. The twelve signs of the zodiac: ♈ Aries; ♉ Taurus; ♊ Gemini; ♋ Cancer; ♌ Leo; ♍ Virgo; ♎ Libra; ♏ Scorpio; ♐ Sagittarius; ♑ Capricornus; ♒ Aquarius; ♓ Pisces.—In *Algebra*, the first letters of the alphabet, *a, b, c*, commonly denote given magnitudes, while the last letters, *x, y,*

x, &c., stand for unknown magnitudes, which are to be found. Furthermore, + (*plus*) more, — (*minus*) less, signify addition and subtraction; × denotes multiplication, ÷ division, = equality, √ root (*radix*). Also: ° degree; ′ minute; ″ second; ‴ third; &c.—*Chemical Signs:* 🜁 air; 🜃 earth; ∇ water; △ fire; ☽ silver; ☉ gold; ♀ copper; ♂ iron; ♄ lead; ♃ tin; ☿ quicksilver; ⦶ nitre; ⊖ salt; 🜍 sulphur; 🜿 tartar.—*Geometrical and Trigonometrical Signs:* ∟ angle; △ triangle; □ square; ○ circle; ∽ similarity; ‖ or ‡‡ parallel; ≌ equality and similarity, or coincidence; A > B, A greater than B.—Formerly there were more signs and abbreviations used in scientific works than at present. In Prussia, the use of signs in medical prescriptions has been abolished on account of the danger of their being confounded.

Charcoal. For the various processes connected with the manufacture of charcoal, we must refer our readers to the article Carbon. In addition to which there are two facts of some importance, which have since come to hand. The first of these relates to the manufacture of charcoal on the large scale at Goersdorf, in Saxony. It having been suggested by M. Boult, that a superior charcoal might be produced by filling the interstices of the pile with small charcoal, the refuse of former burnings, an experiment was made, which, after being several times repeated, gave the following results; 1st, an increase of produce, amounting to not less than four per cent. above that yielded by the ordinary process; 2nd, a much smaller quantity of dust and small coal; 3rd, scarcely any smoke; 4th, charcoal of a very equal and superior quality.

A pile prepared for carbonization at Goersdorf contained in general about thirty *schragen* (318 cubic yards) of pine trees split in quarters, which yielded, including the small coal, from eighty-nine to ninety-two per cent. in bulk of charcoal. It was considered desirable to ascertain, whether by increasing the size of the pile, a more considerable product would be obtained. A pile containing forty-nine schragen (about 520 cubic yards), of cleft pine wood, gave in an experiment, during which the weather proved favourable, 89.94 per cent. of charcoal (including the small), very sonorous, and of very good quality. A second trial of 69½ schragen (740 cubic yards), of similar wood produced only 87.98 per cent., but the weather in this instance was unfavourable.

This experiment was repeated with seventy-one schragen (752 cubic yards), the weather continuing fine throughout the process; the produce amounted to 94.87 per cent.; equal in quality to the former results. The average results of the adoption of this process at Goersdorf, will appear from the following table of the produce, from the commencement to the date of the latest improvements:

	Produce per cent.		Total Produce per cent.
	Lagre.	Small.	
1821 . .	74.94	3.91	78.85
1822 . .	76.24	4.76	81.—
1823 . .	76.44	5.25	81.69
1824 . .	77.95	4.09	82.04
1825 . .	86.31	4.35	90.66
1826 . .	86.31	3.62	89.93
1827 . .	87.53	4.20	91.73

Another fact, and one of some importance is, that *turf* may, by the common process of carbonization, be converted into charcoal.

Chart. See Map.

Chasing, in *Sculpture;* the art of embossing on metals. This is the art of representing figures, &c., in a kind of *basso relievo*, punched out from behind, and sculptured on the front with small chisels and gravers.

Cheese; a preparation made from the curd of *milk*, which see. The curds are pressed in a mould by means of a strong screw, and all the whey extracted. The residuum forms the cheese of commerce. Its quality principally depends on whether cream, milk, or merely skimmed milk, has been employed in the formation of the curd. The county of Cheshire is said to produce the best cheese in this country, and the Swiss or Gruyere the best imported from abroad.

The immense quantities of cheese imported into this country will be best understood by reference to the parliamentary document which we subjoin:

	Cwt.	qrs.	lbs.
Total quantities imported in one year	189,892	0	12
Rates of duty charged	10*s*. 6*d*. per cent.		
Amount of duty received . . .	£98,668	0	0

Check; a draft or bill on a banking house, to be paid at sight, to the bearer.

Chemistry. In the present article we purpose giving a general history of the progress of chemistry, omitting only those portions, by some called its "golden age," when the dreams of the alchemist promised to open to mankind an inexhaustible supply of the precious metals. Of the amusing reveries of those philosophers, an account has already been given in our article on Alchemy; and the various details of chemical science will be found dispersed through the alphabetical arrangement of the work. By the term chemistry, the etymology of which is uncertain, we understand the science which teaches the nature of bodies, or rather the mutual agencies of the elements of which they are composed, with a view to determine the nature, proportions, and mode of combination of those elements in all bodies. *Natural philosophy*, or *physics*, examines the reciprocal influence of matter in masses. *Chemistry* treats of the mutual action of the integrant parts. In the former, the phenomena are produced by the general attraction or repulsion of bodies; in the latter, by minute combination or decomposition.

With our present knowledge of matter and its laws, we cannot separate physics entirely from chemistry: one science cannot be studied without the other. Those artisans who first discovered the means of melting, combining, and moulding the metals; those physicians who first extracted vegetable substances from plants, and observed their properties, were the first chemists. Instead, however, of observing a philosophical method in their examinations; instead of passing from what was known to what was unknown, early inquirers suffered themselves to be led astray by astrological dreams, the fables of the philosopher's stone, and a hundred other absurdities.

Until the year 1650, we find little worthy of notice in the history of chemistry. Rhazis, Roger Bacon, Arnaud de Villeneuve, Basilius Valentin, Paracelsus, Agricola, &c., observed some of the properties of

iron, quicksilver, antimony, ammoniac, saltpetre. They discovered sulphuric, nitric, and other acids; the mode of rectifying spirits, preparing opium, jalap, &c., and of purifying the alkalies. Glauber was distinguished for the accuracy of his observations. He endeavoured to improve certain instruments; advised operators not to throw away any residuum, in performing experiments, as useless; discovered the salt which is called, from him, *Glauber's salt*, &c. Such isolated discoveries, however, could not form a complete science. Stahl appeared, and although his theory was unsatisfactory and entirely gratuitous, and as later observations have proved, erroneous, yet he laid the foundations of a regular science. He was himself much indebted to the celebrated Becher, whose views he corrected and extended. He was sensible that the greater part of chemical phenomena might depend on a general cause, or at least on a few general principles, to which all combinations must necessarily be referred. He supposed that bodies contained a combustible element, which inflammable bodies lost by being burned, and which they could regain from other more inflammable bodies. This element he called *phlogiston*. The establishing of a hypothesis, which connected almost all phenomena with each other, was an important step. Boerhaave adopted Stahl's system, and contributed much to its general diffusion. He is the founder of philosophical chemistry, which he enriched with numerous experiments, in regard to fire, the caloric of light, &c. Although the principles on which those philosophers proceeded were false, yet the science was much advanced by their labours. It was reserved for Black, Priestley, Cavendish, and Lavoisier to overturn Stahl's system, and substitute the pneumatic or antiphlogistic chemistry, the best history of which is to be found in Fourcroy's *Philosophie Chimique*, and his *Système des Connaissances Chimiques*.

As soon as the composition of the atmospheric air was known, it was observed that combustible bodies, burning in contact with it, instead of losing one of their elements, absorbed one of the component parts of the air, and were thus increased in weight. This component part has received the name of *oxygen*, because many of the combustible bodies are changed by its absorption into acids. Oxygen now took the place of phlogiston, and explained the difficulties which beset the phlogistic theory. Light and unity were introduced into chemistry by the new technical nomenclature adopted in 1787, by the aid of which all the individual facts are easily retained in the memory, since the name of each body is expressive either of its composition or of its characteristic property. Twelve or fifteen terms have been found sufficient for creating a methodical language, in which there is no inexpressive term, and which, by changing the final syllables of certain names, indicates the change which takes place in the composition of the bodies. Lavoisier, Fourcroy, Guyton de Morveau, and Berthollet were the authors of this felicitous innovation. The chemical terminology admits of nothing arbitrary, and is adapted not only to express known phenomena, but also any which may be hereafter discovered. It is the first example of a systematic and analytic language.

The commencement of the 19th century forms a brilliant era in the progress of chemistry. The galvanic apparatus of Volta presented to the experimentor an agent unequalled in the variety, extent, and energy of its action upon common matter. With this apparatus, Sir Humphry Davy commenced a series of researches, which resulted in a greater modification of the science than it had ever before experienced. He proved that the fixed alkalies were compounds of oxygen with metallic bases, and thus led the way to the discovery of an analogous constitution in the alkaline earths. To the same individual the science is principally indebted for the establishment of the simple nature of chlorine, and for the investigation of iodine. His researches concerning the nature of flame, resulting as they did in the invention of the miner's safety-lamp, afforded to mankind a new demonstration of the utility of philosophy in contributing to the improvement of the arts of life.

But that department of chemistry which has of late been most successfully investigated, relates to the definite proportions in which bodies unite to form the various chemical compounds. To establish the conclusions which have been arrived at, a multitude of exact analyses were requisite. These were accomplished principally through the labours of Vauquelin, Gay-Lussac, Thénard, Berzelius, and Thompson: and have terminated in the establishment of the general truth that, when bodies combine chemically and intimately with each other, they combine in determinate quantities; and that when one body unites with another in more than one proportion, the ratio of the increase may be expressed by some simple multiple of the first proportion. Upon this general fact, Dr. Wollaston constructed the logametric scale of chemical equivalents—an invention which has contributed in an eminent degree to render our knowledge of the constitution of compounds precise, by introducing the sure basis of arithmetical relations, which, when fixed with accuracy, are not susceptible of change. The doctrine of definite proportionsmay therefore be regarded as having communicated to the principles of chemistry that certainty which has long been considered as peculiar to the mathematical sciences; and it is in the developement of these important relations that the advancement of the science has been most conspicuous.

Among the still more recent improvements in chemistry may be cited the discovery of Döbreiner, relating to the power of platinum in effecting the combination of oxygen and hydrogen; the researches of Faraday, in which many of the gases have been reduced to the liquid form; the discovery of new compounds of carbon and hydrogen, and the singular fact, which they exhibit, of different combinations being established in the same proportions; the elucidation of the new compounds of chlorine with carbon; of the peroxide of chlorine; the hydriodide of carbon; the perchloric, iodous, fulminic, and other acids; the discovery of the real bases of silex and zircon, and that of the new principle, brome: add to these, that our knowledge of light and electricity has been greatly enlarged, and that the phenomena of electro-magnetism are altogether new, and it becomes strikingly obvious that chemistry is still a progressive science. "Nor can any limits be placed to the extent of its investigations. Its analysis is indefinite; its termination will have been attained only when the real elements of bodies shall have been detected, and all their modifications traced: but how remote this may be from its present state we cannot judge. Nor can we, from our present knowledge,

form any just conception of the stages of discovery through which it has yet to pass."

Chemistry has two ways of becoming acquainted with the internal structure of bodies, *analysis* and *synthesis* (decomposition and combination). By the former, it separates the component parts of a compound body; by the latter, it combines the separated elements, so as to form anew the decomposed body, and to prove the correctness of the former process. These methods depend on a complete knowledge of the two powers by which all bodies in nature are set in motion, viz., *attraction* and *repulsion*. Attempts have been made to distinguish the attraction of elementary particles from planetary attraction; the former being designated as *chemical affinity:* but nature has only one kind of attraction. The alternate play of attraction and repulsion produces a great number of sensible phenomena, and a multitude of combinations, which change the nature and the properties of bodies. The study of these phenomena, and the knowledge of these combinations, appertain to the department of chemistry. The history of a body must always precede its analysis. The mere examination of its form, its colour, its weight, and the place where it was found, &c., is often sufficient, by a comparison, to lead to a knowledge of its chemical properties.

There is no science more extensive than chemistry, nor is it possible for one person to embrace it in its whole extent. To facilitate the study, it is considered in different points of view, and thrown into divisions and subdivisions, so that a person may devote himself to one department of it, although the method of observing, analyzing, and combining, is the same in all, and although all the phenomena must be explained by the general theory, and refer to certain laws, of which a previous knowledge is requisite. These laws constitute what is called *philosophical* chemistry, which explains what is meant by the affinity of aggregation or cohesion, and by the affinity of composition or chemical affinity. It treats of the phenomena of solution, saturation, crystallization, ebullition, fusion, neutralization. Chemical processes, by changing or modifying the properties of bodies, suggest to the observer important considerations on the changes of form, density, and temperature.

Philosophical chemistry weighs these considerations. It shows farther, that affinity may be exerted, 1. between two simple bodies; 2. between a simple and a compound one; 3. between compound bodies; and establishing the principle, that the same body has not the same affinity for all others, but attracts them unequally; it shows us the laws which determine this preference, and the circumstances which modify it; such as cohesion, mass, insolubility, elasticity, and temperature. It measures the degree of affinity, whether of simple or compound bodies. It observes the circumstances which aid or obstruct the play of attraction, and shows that two bodies will not act upon each other, unless one of them at least, is in a fluid state; that bodies even in a state of solution, act upon each other only at imperceptible distances; that two bodies, which have perceptible affinity, may be made to combine by the interposition of a third; and finally, that the peculiar properties of bodies are destroyed by their combination, and the compound possesses entirely new properties.

Proceeding from these principles to the examination of bodies themselves, philosophical chemistry considers the effects of light, heat, and electricity; the nature of the simple and compound inflammable bodies; of air and water; the composition and decomposition of acids; the nature and properties of the salts; their relations to the acids; the calcination, solution, and alloying of metals; the composition and nature of plants; the characteristics of the immediate elements of vegetable substances; the phenomena of animalization; the properties of animal compounds, and the decay of organic substances. This is the sphere of philosophical chemistry, while it confines itself to general views.

According to the application of these general views, chemistry is divided into seven or eight branches, which we have yet briefly to survey. The study of the great phenomena which are observed in the atmosphere, and which are called *meteors*, constitutes *meteorological* chemistry. This explains the formation of the clouds, rain, mist, snow, water-spouts; the state of the atmosphere in relation to the hygrometer, barometer, and thermometer; the nature of the aurora borealis, meteoric stones; in short, all the chemical processes going on above the surface of the earth. *Geological* chemistry treats principally of the great combinations of nature, which produce volcanoes, veins of metals, beds of mineral coal, basalt, mineral waters, the enormous masses of salt and lime, the saltpetre in the bed of the Indus, the natron of the lakes of Egypt, the borax of the lakes of Thibet. The geological chemist endeavours to discover and explain the causes of deluges, earthquakes, the decrease of the waters on the globe, the influence of climate on the colour of animals and plants, on the smell of flowers, and the taste of fruits. In these general views, he needs the aid of natural philosophy and physics. Chemistry, in its application to natural history, is divided in the same manner. There is a chemistry of the mineral kingdom, which comprises metallurgy and assaying, and the examination of all the inorganic substances, as stones, salts, metals, bitumen, waters; a chemistry of the vegetable kingdom, which analyzes plants and their immediate products; and a chemistry of the animal kingdom, which studies all substances derived from living or dead animals. This last is subdivided into *physiological* chemistry, which considers the changes produced in animal substances by the operation of life; *pathological* chemistry, which traces the changes produced by disease or organic defects; *therapeutic* or *pharmaceutic* chemistry, which teaches the nature and preparation of medicines, shows the means of preserving them, and exposes the pretensions of empirics; *hygietic* chemistry, which acquaints us with the means of constructing and arranging our habitations, so as to render them healthy, of examining the air which we must breathe in them, guarding against contagious diseases, choosing wholesome food, discovering the influence of occupation, fashion, and custom on the health.

Agricultural chemistry treats of the nature of plants and soils, and the laws of production. Sir Humphry Davy first gave it the character of a science. It treats, 1. of the general powers of matter which have any influence on vegetation, of gravity, cohesion, chemical affinity, heat, light, electricity, the elements of matter, especially such as are

found in vegetables, and the laws of their composition and arrangement; 2. of the organization of plants, their structure, the chemical composition of their organs, and the substances found in them, &c.; 3. of soils; 4. of the nature of manure.

Chemistry, finally, exerts an influence on the routine of domestic life, and on the arts. It simplifies and regulates the daily offices of the housekeeper; renders our dwellings healthy, warm, light; assists us in preparing clothing, food, drink, &c.: it teaches the best way of making bread; preparing and purifying oils; of constructing bake-houses, ovens, and hearths; of bleaching and washing all kinds of stuff; of producing artificial cold, &c. The application of chemistry to the arts and manufactures is, however, still more important and extensive. Here its aim is to discover, improve, extend, perfect and simplify the processes by which the objects to be prepared may be adapted to our wants. We close our remarks with the observation, that a knowledge of chemistry may frequently be useful in judicial proceedings, in exposing crime; in cases of poisoning, counterfeiting coins and written documents, &c.

Chemical Classification and Nomenclature. The chemist finds a small number of bodies, from which only one kind of matter can be obtained, in the present state of his knowledge, and by the instruments and agents which he now has at his disposal. On the other hand, there is a large number of bodies, from which he obtains several kinds of matter. The former he calls *elements*, or *simple bodies;* the latter, *compound bodies.* The number of simple bodies now known is scarcely more than fifty: that of the compounds is much greater, and might at first appear to be infinite, since not only a difference of elements, but even a difference of the proportions in which they are combined, makes an essential difference in the properties of the compound. It is, however, much less than would be supposed, and even less than the number of possible combinations of simple bodies. Twelve of the simple bodies are oxygen, iodine, chlorine, bromine, fluorine, hydrogen, boron, carbon, phosphorus, sulphur, azote, and selenium; and forty-one are metals. The five first are called *supporters of combustion,* because they combine with the others, producing a disengagement of heat and light, and *acidifying principles,* because they are also capable of producing acids by a similar combination. The others are called *simple combustibles,* because their union with the supporters of combustion, above mentioned, is a real combustion. Compound bodies, as has been observed, are not so numerous as might be supposed. They result, 1. from the combination of oxygen, or one of the other simple supporters of combustion, with one of the simple combustibles; such are the acids: 2. from that of a simple body combined with oxygen, with another similar compound; such are the salts: 3. from that of two, three, rarely four, simple combustibles with one another: 4. from that of oxygen with hydrogen and carbon, forming vegetable matter: 5. from that of oxygen with hydrogen, carbon and azote, forming animal matter.

Combustibles combined with the simple supporters of combustion are sometimes called *burned bodies;* from the number of their elements they are also called *binary compounds.* When their taste is acid, and they have the property of reddening vegetable blues, they are termed *acids.* If they are not acid to the taste, and have the property of turning blue what has been reddened by acids, they are distinguished by the termination *ide,* as *oxide, chloride,* &c. If only one of the latter class is formed, that is, if the supporter of combustion will unite with the combustible in only one proportion, we call this compound simply the *oxide, chloride,* &c., of the combustibles; as *oxide of carbon.* If they unite in several proportions, we call the first, or that which contains the smallest proportion of oxygen, &c., *protoxide,* &c., the second, *deutoxide;* the third, *tritoxide.* The highest is also called *peroxide.* So, if only one acid is formed, we designate it by the name of the combustible, with the termination *ic.* Thus carbon with oxygen forms *carbonic* acid. If several are formed, that which contains the larger proportion of the acidifying principle is designated by the termination *ic,* and that which contains less, by the termination *ous.* Thus sulphur forms *sulphuric* acid and *sulphurous* acid. If there are still intermediate compounds, we annex *hypo* (signifying *less*), to designate a lower degree of acidity. Thus we should have *sulphuric, hyposulphuric; sulphurous, hyposulphurous.* In the acids and oxides, chlorides, &c., the combustible is called the *base.* When the base is the same, the peroxide, &c., always contains less oxygen, &c. than the lowest acid. For the names of compounds of two binary burnt bodies, no rules have been adopted to express the union of two oxides, two acids, or an acid with a non-metallic oxide. But those formed of acids and metallic oxides are called *salts,* and their individual names are formed by changing the termination of the acid and placing it before the name of the metal; the termination *ous* is changed into *ite,* and *ic* into *ate;* sulphurous acid with the oxide of tin would form *sulphite of tin;* sulphuric acid and tin, *sulphate of tin.* If the same acid combines with more than one oxide of the same metal, then we prefix the characteristic of the oxide to the name of the acid; thus sulphuric acid, combined with the protoxide of iron, forms the *protosulphate,* with the peroxide, the *persulphate,* of iron. Other substances have also the property of uniting with acids, neutralizing them, and forming compounds analogous to salts. There are no general rules for the names of these compounds; but the substances themselves are called *salifiable bases.*

The rules of nomenclature, in regard to the combination of the combustibles, vary:—1. If the constituents are metals, they form *alloys.* 2. If the compounds are solid or liquid, and formed of a metallic and a non-metallic combustible, we give to the latter the termination *uret;* as, carbon with iron forms *carburet of iron.* If both are non-metallic, the termination *uret* may be attached to either; as, *phosphuret of sulphur,* or *sulphuret of phosphorous.* 3. If the compound is gaseous, we name the gas, or one of the gases if it is composed of two, and join the other component as an adjective; as, *phosphurated hydrogen.*

CHESS; the most celebrated and general of all sedentary games. One of the greatest charms of chess lies, no doubt, in the circumstance, that whilst man is everywhere surrounded by chance, in this game, as generally played, he has entirely excluded it, except that it must be decided by chance which of the two players shall begin. The game affords so much variety, so much scope for calculation, so many oppor-

tunities to exhibit foresight and penetration, that it has been held in great esteem by all nations acquainted with it, and all persons who have conquered the difficulties of learning it. The Mahommedans except chess from the law against gambling. Whilst this game affords enjoyment worthy of mature minds, it is an excellent exercise for the young, as it teaches patience and circumspection, strengthens the judgment, and encourages perseverance in a plan affording a prospect of eventual success, though at the moment the situation of things may appear very critical.— The Chinese pretend to have known it 200 years previous to our era. It was brought in the sixth century from India to Persia, whence it was spread by the Arabians and the crusaders all over the civilized world. It is most commonly used in Asia. In fact its whole composition and its name prove its Asiatic origin. In Sanscrit it is called *schthrantsh*, a word which is believed to indicate the most important component parts of an ancient Eastern army—elephants, infantry, baggage-waggons, and horses. But this name was supplanted by the Persian term *shah* (king); which the game has retained, more or less corrupted, in all languages. A proof of the great antiquity of the game of chess in this island will be found in the curious discovery which was made in Scotland in 1831. A number of ancient chess-men were found, which are now deposited in the British Museum. They are carved from the tusk of the walrus, and we give a view of the king, which is also curious, as a specimen of early art.

Generally, chess is played by two persons upon a board, the same as that used in draughts or chequers, containing 64 squares. The board must be so placed that each player has a white square at his right hand. The squares are named from the pieces, viz.: that on which the king is placed is called the *king's square;* that on which the king's pawn is placed, the *king's second square;* that before the pawn, the *king's third square;* the next, the *king's fourth;* and so on with all the pieces of each side. Each player has eight pieces and eight pawns. In placing the pieces, the ancient rule is to be followed—*servat regina colorem* (the queen maintains the colour)—that is, the black queen is to be placed on the black square in the middle of the line next to the player; in a similar way the white queen on the white field. On the side of the king and the queen stand the bishops; then follow the two knights; and last, the rooks or castles. The object of the game is to bring the adversary's king into such a situation that he cannot move, which is called *checkmating*. The king can never be taken. The play ends with a checkmate.—(It is related of Dr. Franklin, that once playing chess in Paris, and being checkmated, he said, "Take the king; I am a republican, and don't care for him.") It is not uninteresting to consider the different names which the pieces have received in various countries. In the East the queen is called by the more proper name of *vizier* or *general*.

The bishops are called in Germany *runners;* and in France *fools (fous)*. These were originally elephants, with giants on them. The knights are called in German *leapers*. The castles were originally *war-chariots*, which is also indicated by the word *rook*, from the Indian *roch* or *roth*. With the old Germans the pawns, now called *peasants*, were styled *Wenden* (Vandals), a tribe despised by the Germans. Don John of Austria had a room, the floor of which was made like a chess board. On this he played with living persons. The peasants of a German village, Stropke, or Strobeck, near Halberstadt, for about 300 years, have been distinguished as chess players. The reason for this is doubtful. The most probable opinion is, that a certain bishop who lived among them made them acquainted with this game, and freed them from several taxes on condition that they would continue to practice it.

Numerous anecdotes show how much the game of chess can absorb the mind. The Elector of Saxony, John Frederick, was taken prisoner in the battle at Mühlberg by the emperor Charles V., and was playing at chess with his fellow-prisoner, Ernest of Brunswick, when it was intimated to him that the emperor had sentenced him to death. He paused for a moment to remark on the irregularity of the proceeding, and immediately resumed the game, which he won, and expressed in a lively manner the pleasure which he derived from his victory. Charles XII. of Sweden played at chess when he was so closely besieged in the house near Bender, by the Turks. Al Amin, caliph of Bagdad, would not be disturbed in chess-playing when the city was carried by assault. Frederick the Great loved chess much. Napoleon did not play it particularly well.

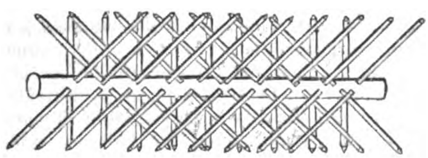
Among the most famous players and writers on the game are, a duke of Brunswick, named *Augustus*, who in the 17th century published, under the name of *Selenus*, an introduction to the game (1616, 4to.), now very rare; Philidor, a Frenchman, who was particularly distinguished in London in 1780—90; Gioacchino Greco, celebrated in the beginning of the 17th century; and the Arabian Philip Stamma in Paris, 1737. Caxton's "*Game and Playe of the Chesse*," printed in 1474, is generally admitted to be the first typographical work executed in England.—*Anastasia*, a German novel by Heynse, contains many ingenious ideas on chess-playing, and several fine games. Some very curious manuscripts relating to this game, in the Chinese, Sanscrit, Persian, and Arabic languages have been partially translated; and the presses of Europe have teemed with similar productions, the most noted of which are enumerated by Mr. Lewis, in the preface to his edition of *Saratt on Chess*, 1822.

Laws of the game.—1. If the board, or pieces, be

improperly placed, the mistake cannot be rectified after four moves on each side are played. 2. When a player has touched a piece, he must move it, unless it was only to replace it; when he must say, *J'adoube*, or *I replace*. 3. When a player has quitted a piece, he cannot recal the move. 4. If a player touch one of his adversary's pieces without saying *J'adoube*, he may be compelled to take it, or, if it cannot be taken, to move his king. 5. When a pawn is moved two steps, it may be taken by any adversary's pawn which it passes, and the capturing pawn must be placed in that square over which the other leaps. 6. The king cannot castle if he has before moved, if he is in *check*, if in castling he passes a check, or if the rook has moved. 7. Whenever a player *checks* his adversary's king, he must say *Check*, otherwise the adversary need not notice the check. If the player should on the next move attack the queen, or any other piece, and then say *Check*, his adversary may replace his last move, and defend his king. 8. When a pawn reaches the first row of the adversary's side, it may be made a queen, or any other piece the player chooses. 9. If a false move is made, and is not discovered until the next move is completed, it cannot be recalled. 10. The king cannot be moved into check, nor within one square of the adverse king, nor can any player move a piece or pawn that leaves his king in check.

Chest (called, in anatomical language, the *thorax*) is the cavity of the body between the neck and the belly. The external parts of the thorax are the skin, the breasts, various muscles, and the bones which form the frame of the cavity. These are the sternum, running from the neck down the middle of the breast, and the ribs, which are inserted in the spine, and arched towards the sternum, with which they are firmly connected by means of a cartilage. The parts within the cavity of the thorax are the pleura and its productions, the lungs, heart, thymus gland, œsophagus, thoracic duct, arch of the aorta, part of the vena cava, the vena azygos, the eighth pair of nerves, and part of the great intercostal nerve.

Chevaux de Frise (*Friesland horses*, so called because first used at the siege of Groningen, in that province, in 1658); an armed beam of square timber or iron, used to defend the fronts of camps, breaches, &c. They are usually from 15 to 18 feet long, and connected by chains, each being perforated with small holes, to receive rods of wood or iron, pointed at their extremities, and when moved in any direction, affording a sort of hedge of spears. An arrangement of this kind is shown in the accompanying engraving.



Chiaro Scuro (an Italian phrase, meaning *clear-obscure*; in French, *clair-obscur*), in *Painting*, is the art of judiciously distributing the lights and shadows in a picture. A composition, however perfect in other respects, becomes a picture only by means of the *chiaro scuro*, which gives faithfulness to the representation, and therefore is of the highest importance for the painter; at the same time, it is one of the most difficult branches of an artist's study, because of the want of precise rules for its execution. Every art has a point where rules fail, and genius only can direct. This point in the art of painting is the *chiaro scuro*. The drawing of a piece may be perfectly correct, the colouring may be brilliant and true, and yet the whole picture remain cold and hard. This we find often the case with the ancient painters before Raphael; and it is one of the great merits of this sublime artist, that he left his masters far behind him in *chiaro scuro*, though he is considered not so perfect in this branch as Correggio and Titian, who were inferior to him in many other respects. The mode in which the light and shade are distributed on any single object is easily shown by lines supposed to be drawn from the source of the light which is shed over the figure; but *chiaro scuro* comprehends besides this, aerial perspective, and the proportional force of colours, by which objects are made to advance or recede from the eye, produce a mutual effect, and form a united and beautiful whole.

Chiaro scuro requires great delicacy of conception and skill of execution; and excellence in this branch of art is to be attained only by the study of nature and of the best masters. *Chiaro scuro* is also understood in another sense, paintings in *chiaro scuro* being such as are painted in light and shade and reflexes only, without any other colour than the local one of the object, as representations of sculpture in stone or marble. There are some fine pieces of this sort in the Vatican at Rome, by Polidoro da Caravaggio, and on the walls of the staircase of the Royal Academy of London, by Cipriani and Rigaud.

Chilblains are painful inflammatory swellings, of a deep purple or leaden colour, to which the fingers, toes, heels, and other extreme parts of the body are subject on being exposed to a severe degree of cold. The pain is not constant, but rather pungent and shooting at particular times, and an insupportable itching attends it. In some instances, the skin remains entire; but in others, it breaks and discharges a thin fluid. When the degree of cold has been very great, or the application long continued, the parts affected are apt to mortify, and slough off, leaving a foul, ill-conditioned ulcer behind. Children and old people are more apt to be troubled with chilblains than persons of middle age; and such as are of a scrofulous habit are remarked to suffer severely from them.

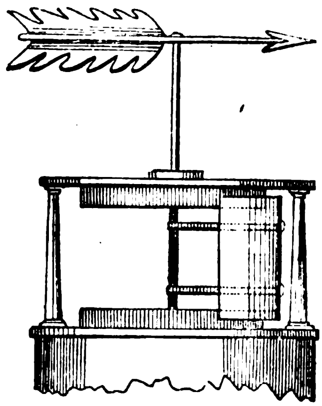
Chimes, in horology, is a species of music, mechanically produced by the strokes of hammers against a series of bells, tuned agreeably to a given scale in music. The hammers are lifted by levers, acted upon by metallic pins, or wooden pegs, stuck into a large barrel, which is made to revolve by clock-work, and is so connected with the striking part of the clock mechanism, that it is set in motion by it at certain intervals of time, usually every hour, or every quarter of an hour. The music thus produced may consist of a direct succession of the notes constituting an octave frequently repeated, or otherwise may be a psalm tune, or short popular air in the key to which the bells are tuned. This species of mechanical music most probably had its origin, like clock-work itself, in some of the monastic institutions of Germany, in the middle ages. The first apparatus for producing it is said to have been made at Alost, in the Netherlands, in 1487. The chime mechanism may be adapted to act with the large bells of a church

steeple by means of wheel-work strong enough to raise heavy hammers; or a set of bells of different diameters, may be arranged concentrically within one another on one common axis, sufficiently small to be introduced into the frame of a clock, or even of a watch. The chime mechanism is sometimes so constructed, that it may be played like a piano, but with the hand instead of the fingers. This is covered with leather, that the blow on the key may be applied more forcibly. Difficult as the performance is, some players can execute compositions consisting of three parts, and even produce trills and *arpeggios*. Burney relates that the chime-player Scheppen, at Louvain, laid a wager with an able performer on the violin, that he would execute a difficult solo for the violin with the bells, and won his wager. Pottheff, organist and chime-player at Amsterdam, became blind in his 7th year, and received the above-named appointment in his 31st year; and although every key in his apparatus required a force equal to a two-pound weight, yet he played his bells with the facility of a performer on the piano-forte. Burney heard him perform some fugues in 1772.

CHIMNEY. How far the Greek and Roman architects were acquainted with the construction of chimneys, is a matter of dispute. No traces of such works have been discovered in the houses of Pompeii, and Vitruvius gives no rules for erecting them. The first certain notice of chimneys, as we now build them, is believed to be that contained in an inscription at Venice, over the principal gate of the *Scuola Grande di Sta. Maria della Carità*, which states that, in 1347, a great many chimneys were thrown down by an earthquake. Chimneys require much attention to make them secure and prevent their smoking, so great an annoyance to domestic comfort. It seems at present to be acknowledged, that it is much better to exclude the cold damp air from the flues, by narrowing the aperture at the top, than to give a larger vent to the smoke, at the risk of admitting a quantity of air to rush down the flue. For this reason, chimney-pots are of great use. In Prussia, where the architectural police (*Baupolizei*) is strict, great attention is paid to the erection of chimneys, and to the regular sweeping of them, the chimney-sweepers being bound to sweep the chimneys of a certain number of streets within a regular time; and, though the interference of a police in subjects of domestic economy is a delicate matter, the numerous fires which take place in other countries, from the careless construction of chimneys, seem to make some public supervision of their security desirable. The longer a chimney is, the more perfect is its draught, because the tendency of the smoke to draw upwards is in proportion to the different weight of the column of air included in a chimney and an equal column of external air. Short chimneys are liable to smoke, and fire-places in upper stories are, therefore, more apt to smoke than those in the lower ones. Two flues in the same chimney should not communicate with each other short of the top. Some chimneys, in large establishments in London, are very remarkable for their size.

The inconvenience which arises from the action of currents of air impeding the ascent of smoke, and as such diminishing the draught of the fire, has suggested the use of various contrivances to remedy this defect in chimneys. The one generally adopted is called a "revolving hood," which is defective on account of its weight. A lighter apparatus, similar in principle, but turning with less friction, has been the subject of a patent. It consists of a shield connected to a vane, which being turned round with the vane, protects the top of the chimney from any sudden gust of wind, and thereby enables the smoke to pass off without obstruction.

The accompanying figure shows the construction of the apparatus, the chimney-top being covered with an iron plate, having a circular opening in the middle for the passage of the smoke. There is a central shaft bearing on a cross bar at bottom, and carrying the vane at top. The upper plate is supported by pillars, upon which plate there are three anti-friction rollers touching the central shaft, and enabling it to turn in its bearing with very little friction. There are two arms extending from the central shaft to which the curved plate is affixed, constituting a shield.



The vane may be an arrow, or any other figure, which turning its point to the wind, carries round the guard into that situation which is exactly opposed to the wind, and thereby effectually prevents the wind blowing down the throat of the chimney; and of consequence enables the smoke to pass away freely into the atmosphere.

The form of the wind-guard may be varied; that shown in the figure is about one-third of a cylinder; it may, however, be straight, or at an obtuse angle bending inwards. It is farther proposed to place a bevel pinion on the central shaft which shall take into another pinion, on an horizontal shaft, and by that means cause two guards adapted to distinct chimneys to act simultaneously by the agency of one vane. The patentee proposes to form the plates and frame of the apparatus of cast iron, for the sake of cheapness and durability, and the shaft and guard of wrought iron or copper.

CHINA WARE. See PORCELAIN.

CHIRAGRA; that species of arthritis, or gout, which attacks the joints of the hand (the wrist and knuckles) and hinders their motions. It gradually deprives the hands of their flexibility, and bends the fingers, distorts them, and impedes their action, by the accumulation of a calcareous matter around the sinews, which finally benumbs and stiffens the joints.

CHIROLOGY; the language of the fingers, or the art of making one's self understood by means of the hands and fingers. It is an important means of communication for the deaf and dumb.

Chiromancy, or **Palmistry**; the pretended art of prognosticating by the lines of the hand. Its adherents maintain that human inclinations, faults, and virtues are designated in an infallible manner by the lines which divine Providence has originally drawn in the hands of all men. Traces of chiromancy are found in the writings of Aristotle, who asserts, for instance, that it is a sign of a long life if one or two lines run across the whole hand. The chiromancers quote some passages of the Bible to prove that their art is founded on the divine decrees, as the following:—"And it shall be for a sign unto thee upon thine hand, and for a memorial between thine eyes." (*Exodus* xiii. 9); and "He sealeth up the hand of every man, that all men may know his work." (*Job* xxxvii. 7.) In the middle ages chiromancy was cultivated; and, in the present age, the French chiromancer, Madame Lenormand, found, as she states, some eminent adepts in Paris, and in her travels to the different European congresses. The books in which chiromancy is explained and taught are numerous; and, in order to give dignity to the art, it has been connected with astrology. The gipsies are at present the principal professors of chiromancy, and people who have no faith in the art not unfrequently amuse themselves with their predictions.

Chlorine Acid. See Chlorine.

Chloride of Nitrogen. See Chlorine.

Chlorine. The discovery of this gas was made in 1770, by Scheele, and named by its discoverer, *dephlogisticated marine acid*. The term *dephlogisticated* had exactly the same import as that of *oxygenated*, soon afterwards introduced by Lavoisier. From its peculiar yellowish-green colour, the appellation of *chlorine* (from χλωρὸς, green) has been given to it. Chlorine gas is obtained by the action of muriatic acid on the peroxide of manganese. The most convenient method of preparing it is by mixing concentrated muriatic acid, contained in a glass flask, with half its weight of finely-powdered peroxide of manganese. On the application of a moderate heat, the gas is evolved, and should be collected in inverted glass bottles, filled with warm water. In order to comprehend the theory of this process, it must be premised that muriatic acid consists of chlorine and hydrogen. The peroxide of manganese is composed of manganese and oxygen. When these compounds react on one another, the peroxide of manganese gives up a portion of its oxygen to the hydrogen of the muriatic acid, in consequence of which water is generated, and chlorine (the other ingredient in muriatic acid) is liberated.

The method which is employed in the arts, and which is the most economical, is the following:—Three parts of common salt (muriate of soda) are intimately mingled with one of the peroxide of manganese, and to this mixture two parts of sulphuric acid, diluted with an equal weight of water, are then added. By the action of sulphuric acid on the muriate of soda, muriatic acid is disengaged, which reacts as before explained upon the peroxide of manganese; so that, instead of adding muriatic acid directly to the manganese, the materials for forming it are employed. Chlorine is gaseous under a common atmospheric pressure. It is twice and a half heavier than atmospheric air, or its specific gravity is 2.5. The gas has a yellowish-green colour. Of all the gases, it is the most insupportable in its action on the lungs.

When pure, it occasions immediate death if an animal is immersed in it; and even when largely diluted with common air, it cannot be respired with safety. It occasions a severe sense of stricture at the breast, which renders it impossible to make a full inspiration. This continues for a considerable time after it has been inspired, and has often produced a permanently injurious effect. When thoroughly dried, by exposure to fused chloride of calcium, it suffers no change, though cooled to 40°. When prepared over water, however, so as to contain a quantity of aqueous vapour, it condenses on the sides of the vessel even at a temperature of 40°; and if surrounded by snow or ice, it shoots into acicular crystals of a bright-yellow colour, and sometimes two inches in length, which remain attached to the sides of the vessel. This solid is a hydrate of chlorine, and, when heated to 50°, it melts into a yellowish oily fluid. Chlorine is absorbed by water, in a quantity which increases as the temperature diminishes. At 50°, the water takes up about twice its volume. The solution has a yellowish-green colour, and its odour is that of the gas itself. Its taste is rather styptic than sour, and the liquid, like the gas, has the property of destroying the vegetable colours. Hence it may be employed in bleaching. It is not changed by a boiling temperature. Solution of chlorine is decomposed, however, by exposure to the solar light; the chlorine attracts hydrogen from the water, forming muriatic acid, which remains dissolved, and pure oxygen is disengaged. Chlorine gas supports the combustion of a number of inflammable substances. A lighted taper burns in it, though feebly, with a red flame; phosphorus takes fire when immersed in it; and a number of the metals, as antimony, arsenic, copper, and others, if introduced into it in leaves or filing, burn spontaneously. Potassium and sodium burn vividly in it. In these cases, the inflammable or metallic substances are believed simply to unite with the chlorine.

Chlorine combines with many of these bases in more than one proportion. When in one proportion, the compound is called a *chloride;* when in two, a *bi-chloride*, or a *deuto-chloride*, &c. Whenever a metallic chloride, which is soluble in water, is thrown into that fluid, it is conceived to be instantly converted into a muriate; the water present is decomposed, its oxygen goes to the metallic base, and its hydrogen to the chlorine, and a muriate of an alkali, earth, or metallic oxide, is formed. Thus common salt when dry, is a chloride of sodium; it is no salt, containing neither acid nor alkali, but whenever it is dissolved in water, it is immediately transformed into a salt: the sodium attracts oxygen and becomes soda, and the chlorine takes hydrogen and becomes muriatic acid, and muriat of soda exists in the solution.

When any of the compounds of chlorine, with inflammable substances or metals, are subjected to the action of a galvanic apparatus sufficiently powerful to decompose them, the chlorine is always evolved at the positive pole of the battery, and the base at the negative pole. In this respect, and in its power of supporting combustion, chlorine is analogous to oxygen. One of the most important chemical properties of chlorine is displayed in its action on the vegetable colours. Many of them it entirely destroys; and even those which are the most deep and perma-

nent, such as the colour of indigo, it renders faint, and changes to a light yellow or brown. This agency is exerted by it, both in its gaseous and its liquid form. The presence of water is, however, necessary to this. Hence, when the gas destroys colour, it must, probably, be enabled so to do by the hygrometric water it contains. It is accordingly found, that when freed from this, it does not destroy the colour of dry litmus paper.

The destruction of colour appears to be owing to the communication of the oxygen of the water present to the colouring matter: the chlorine attracts the hydrogen of the water to form muriatic acid, and the evolved oxygen unites with the colouring matter, and by changing its constitution, alters its relation to light, so that the tint disappears. Berthollet applied this agency of chlorine to the process of bleaching, and with such success as to have entirely changed the manipulations of that art. The method of using it has been by Mr. Hall improved. It consisted at first, in subjecting the thread or cloth to the action of the gas itself; but the effect in this way was unequally produced, and the strength and texture were sometimes injured. It was then applied, condensed by water, and in a certain state of dilution. The thread or cloth was prepared as in the old method of bleaching, by boiling first in water, and then in alkaline lye; it was then immersed in the diluted chlorine; this alternate application of alkali and chlorine was continued until the colour was discharged. The offensive, suffocating odour of the gas rendered this mode of using it, however, scarcely practicable; the odour was found to be removed by condensing the chlorine by a weak solution of potash: lime, diffused in water, being more economical, was afterwards substituted. Under all these forms, the chlorine, by decomposing water, and causing oxygen to be imparted to the colouring matter, weakens or discharges the colour, and the colouring matter appears to be rendered more soluble in the alkaline solution, alternately applied, and of course more easily extracted by its action.

More lately, a compound of chlorine and lime has been employed, prepared by exposing slaked lime to chlorine gas: the gas is quickly absorbed, and the *chloride of lime*, as it is called, being dissolved in water, forms the bleaching liquor now commonly employed, and which possesses many advantages. In using it, the coloured cloth is first steeped in warm water to clean it, and is then repeatedly washed with a solution of caustic potash, so diluted that it cannot injure the texture of the cloth, and which is thrown upon it by a pump; the cloth is then washed and steeped in a very weak solution of chloride of lime, again washed, acted on by a boiling lye as before, and again steeped in this solution; and these operations are performed alternately several times. The cloth is lastly immersed in very dilute sulphuric acid, which gives it a pure white colour; after which it is washed and dried. Chloride of magnesia has been substituted with great advantage for that of lime, in whitening cloth for calico printing; the cloth when lime is used, retaining a little of it, which in the subsequent operation of clearing by immersion in weak sulphuric acid, forms sulphate of lime, which remains and affects the colours when it is dyed; while the sulphate of magnesia is so soluble, that it is entirely removed. Chloride of alumine has been employed to discharge the colour of the Turkey-red dye, which resists the action of other chlorides, and is only discharged by chlorine gas, by an operation very injurious to the workmen.

Another important application of chlorine gas is that of destroying or neutralizing contagion. Acid vapours, sulphurous acid in particular, under the form of the fumes of burning sulphur, had often been employed for that purpose; but chlorine, from the facility with which it decomposes the different compound gases that contain the elements of vegetable and animal matter, and which may be supposed to constitute noxious effluvia, is superior to any other agent, and is now universally employed for the purposes of fumigation. It is the only agent which can administer relief in cases of asphyxia from sulphurated hydrogen; and it has been found useful among such persons as are obliged to frequent places where contagious effluvia are constantly developed, to bathe the hands and arms with its solution. Chlorine, united with hydrogen, forms an important compound, called *muriatic*, or *hydrochloric acid gas*. With oxygen, it gives rise to four distinct compounds, which are remarkable for the feeble attraction of their constituent elements, notwithstanding the strong affinity of oxygen and chlorine for most elementary substances. These compounds are never met with in nature. Indeed, they cannot be formed by the direct combination of their constituents; and their decomposition is effected by the slightest causes. Notwithstanding this, their union is always regulated by the law of definite proportions, as appears from the following tabular view, illustrative of their composition.

	Chlorine.	Oxygen.
Protoxide of chlorine	36	8
Peroxide of chlorine	36	32
Chloric acid	36	40
Perchloric acid	36	56

Chlorine forms, along with nitrogen, one of the most explosive compounds yet known, and was the cause of serious accidents to M. Dulong, its discoverer, and afterwards to Sir H. Davy.

The *chloride of nitrogen* is formed from the action of chlorine on some salt of ammonia, chlorine and nitrogen being incapable of uniting, when presented to each other in their gaseous form. Its formation is owing to the decomposition of ammonia (a compound of hydrogen and nitrogen) by chlorine. The hydrogen of the ammonia unites with chlorine, and forms muriatic acid; while the nitrogen of the ammonia, being presented in its nascent state to chlorine, dissolved in the solution, enters into combination with it. The chloride of nitrogen has a specific gravity of 1.653; it does not congeal by the intense cold produced by a mixture of snow and salt. At a temperature between 200° and 212°, it explodes; and mere contact with most substances of a combustible nature causes detonation at common temperatures. The products of the explosion are chlorine and nitrogen.

Three distinct compounds of *chlorine* and *carbon* have of late been made known by Faraday; but for an account of these, as well as of the *chlorides of sulphur and of phosphorus*, and the *chloro-carbonic acid gas*, the reader is referred to the larger treatises on chemistry, it being incompatible with the plan of the present work to enter into those details which are not connected with the useful arts, or which are not absolutely necessary in order to afford a correct idea of

the mode of reasoning and general theory of the science.

Choc (from the French *choc*, the violent meeting of two bodies), in military language, signifies a violent attack. It is generally applied to a charge of cavalry. To give such an attack its full effect, it is necessary, 1. that the line be preserved unbroken, so that the attack shall take effect at all points at the same time; 2. that the horses be strong and heavy, that their momentum may be great; 3. that the charge be made as swiftly as possible, not merely for the sake of the physical effect, but also of the moral effect which it has on the enemy. This swiftness, however, must be attained gradually, increasing as the distance diminishes. The charge commences with a short trot; a long trot follows; at the distance of 150 paces, this is increased to a gallop; and 50 paces from the enemy, the horse must be put to his speed. A choc, whether successful or not, is of short duration.

Chocolate. See Cacao.

Choir; that part of the church where the choristers sing. In some old churches, the seats of the choristers, and others parts of the choir, are ornamented with admirable carved work.

Cholera; a genus of disease arranged by Cullen in the class *neuroses* and order *spasmi*. It is a purging and vomiting of bile, attended with anxiety, painful gripings, spasms of the abdominal muscles, and those of the calves of the legs. There are two species of this genus:—1. *Cholera spontanea*, which happens in peculiar seasons, without any manifest cause. 2. *Cholera accidentalis*, which occurs after the use of food that digests slowly and irritates. In warm climates it is met with at all seasons of the year, and its occurrence is very frequent. It usually comes on with soreness, pain, distension, and flatulency in the stomach and intestines, succeeded quickly by a severe and frequent vomiting, and purging of bilious matter, heat, thirst, a hurried respiration, and frequent but weak and fluttering pulse. When the disease is not violent, these symptoms after continuing for a day or two, cease gradually, leaving the patient in a debilitated and exhausted state; but where the disease proceeds with much violence, great depression of strength ensues, with cold clammy sweats, considerable anxiety, a hurried and short respiration, and hiccoughs, with a sinking, and irregularity of the pulse, which quickly terminate in death, an event that not unfrequently happens in the space of 24 hours. The appearances generally observed on dissection are, a quantity of bilious matter in the *primæ viæ*; the ducts of the liver relaxed and distended. Several of the viscera have been found in some cases displaced, probably by the violent vomiting.

In the above view of the disease we have treated it as the ordinary spasmodic cholera of this country, which has usually been more or less prevalent in the warmer seasons of the year; but, in the year 1831, Europe was visited by this disease, to an extent more fatal than had ever previously been felt in our climate. Whether or no the disease was contagious, appears still a matter of considerable doubt; but there certainly are many circumstances which would tend to a belief in that doctrine.

The disease was first felt to any extent in India, and the progress of its ravages, with the mode of treatment is well described by Mr. Skinner. He says, "Before we had reached Monghyr, where on the 20th of April we arrived, the cholera morbus broke out in our fleet, and reduced it terribly. Many of the Europeans died as well as the natives, and no evening passed without a funeral. The natives were either thrown overboard or deposited by the banks of the rivers to feed the vultures and the jackals; our own men were more decently buried in such graves as could quickly be scooped in the sand. Towards the end of April the disorder assumed a more alarming appearance, and every hour somebody was seized. Each officer was provided with a mixture, the principal ingredients of which were laudanum and brandy; and, in order that no time might be lost in making for the hospital boats, every vessel on board which a man might fall sick, was desired to bear down upon the nearest budgerow for assistance, when a wine-glass of the cholera mixture was administered. It was a melancholy sight to see five or six boats at a time draw out of the line and hasten towards the nearest officers in their rear. The moment the draught was received the disease in some measure seemed stayed, and the sick boat dropped quietly down to the hospital. It never was considered contagious, nor was any precaution used to separate the affected from the healthy; and we did not find that the remainder of the boat's crew was seized in consequence of any one of them having been attacked by it. It committed its ravages indiscriminately through the fleet. A native on board my budgerow died of the complaint in the course of a few hours; and although all the others were lying around him, it was not communicated to any of them. It has always seemed to me to be confined to particular spots: during the month of October, while we were in Fort William, the men who occupied one end of a lower room in the barracks were seized with it, while in every other part of the building they were perfectly healthy. This room had been undergoing repair, and was not properly flagged; the upper one of course was boarded: this circumstance proves it to have been entirely local; for there was a constant intercourse between all the parties, and it was not conveyed to the other quarters. It at length became general in the fort, which at that season of the year, the period of the breaking up of the rains, it usually does. A regiment of British soldiers on its march from Berhampore to Calcutta, halted one morning in the neighbourhood of a morass, and in a few hours afterwards several men were attacked with the cholera morbus, always the attendant evil of such a place: the commanding officer immediately struck the camp, and moved to about seven miles farther on; here the ground was drier and clearer; the sick men recovered, and there was no farther appearance of the disease. I am not very certain what the opinions of the faculty may be in the East, but as no precautions are taken against contagion, I conjecture they do not consider them necessary. I shall never forget the afternoon of our arrival at Patna: the cholera had been raging some time amongst the native population, and all the dead bodies seemed to have been placed on a clear spot without the city, and under the walls of some rich man's palace. The hot wind blew very violently, and we were long within sight of this place without being able to reach it; the water was very low, and several dead bodies that had been washed from the bank by the river, were stranded on the shallows in its centre. It was the 1st of May, and corruption was most rapid;

every breath of the sirocco blew poison; the scene was indescribable; bodies floated sometimes against our boats, for they were nearly all aground, and remained under the bows for an hour at a time, while others swam uninterruptedly down the stream with flocks of birds upon them; little could be heard but the noise of the vultures tearing off the flesh with their beaks, while the crows jangled in their quarrels for the morsels that fell from them. About sun-set we reached the shore; but, alas! could get no farther than the burial-ground, along the edge of which we were obliged to moor. It was strewed with skulls and "dead men's bones," and the air was pestilence itself. The jackals and the wild dogs skulked away from the mangled limbs as we approached, while the vultures, the very sight of which speaks of the charnel-house, rose from the half-eaten body, and, hovering for a moment above it like evil spirits, descended to the completion of their horrible repast. There were a great number of the Hargila large storks, known by the name of adjutants in India, from their measured step, stalking over the ground; they are always close attendants upon Europeans, and had come from the station of Dinapore to share in the feast that cholera had prepared for them."

On the 26th of June, 1831, 580 persons were attacked in St. Petersburg alone, and out of that number 280 died. The disease continued its ravages, and gradually spread over the whole of Europe. From our own country it passed to America, and though its destructive progress has not been on so extended a base as in Europe, yet the mortality in several of the states of the Union has been of a most fearful character.

We may now give the mode of treatment pursued by one of the most intelligent practitioners who has yet written on the subject of cholera,—we mean Mr. Le Fevre. He says, "the following is the practice I have almost universally adopted in cases of cholera where I have been called in at the commencement. If the patient is robust, the pulse still perceptible, and the system not much reduced by evacuations, I order from six to eight ounces of blood to be drawn from the arm, the patient being first put to bed, in the recumbent posture.

"The following draught is then given: Laudanum and æther, of each twenty-five drops, strong peppermint water, an ounce and half.

"If this be rejected, it should be repeated immediately; if the second be likewise not retained, then a clyster of linseed tea with fifty drops of laudanum should be administered.

"It often happens that the patient after taking the first dose falls asleep, and awakes in perfect health.

"A large sinapism to the abdomen, and bottles of hot water to the feet, should not be omitted; if these means produce speedy relief, an ounce of castor oil should be prescribed as soon as the stomach and bowels are quiet.

"Such is the most successful practice in slight cases, and I believe many a severer attack has been prevented by this method of proceeding; for I had given full directions to many of my patients how to act in case of not immediately finding medical aid, and all the houses I attended were prepared with these draughts.

"It may have happened that some have been taken unnecessarily; but I am convinced that many a case has been cut short by immediately applying to this remedy.

"It would be well if this always succeeded; but often after a short respite the symptoms return, the vomiting continues, accompanied with spasms of the abdominal muscles and calves of the legs.

"In such cases, three grains of bismuth should be given every two hours, and continued till the vomiting has ceased, and the spasmodic action greatly or wholly subsided. The bismuth should then be discontinued, for the symptoms which seemed to demand it have subsided; and in this sense only I considered it useful, and by no means a specific for the disease. If it be continued for any length of time, it is in many cases followed by congestion of the brain.

"If this mode of employing succeeds, as soon as the necessity for continuing it ceases, then the castor oil should be resorted to as in the first-mentioned instance, for this is a *sine qua non*. When the shock is thus broken and the patient begins to recover, nothing farther need be done than to keep the bowels open and return to food gradually, beginning by mucilaginous diet, aud by degrees adding veal and chicken broth to the meal.

"If slight delirium should occur, a few leaches to the temples, and a blister to the back of the neck, will generally relieve it.

"If the means above detailed did not succeed, I have not myself been able to succeed by any other. I do not mean to assert that these are the only means I have employed, nor that nothing more is necessary; but they are those upon which I rely the most, and if employed early in the attack, will often be attended with success.

"Many other symptoms require attention even under this plan of proceeding.

"The cramps may often be relieved by friction with the hands, or with some narcotic and stimulating embrocations.

"The colicky pains which remain afterwards, and are renewed by every attempt to go to stool, are best relieved by clysters of starch and opium.

"Cataplasms of hemlock or henbane applied over the whole surface of the abdomen, and renewed every four hours, are of much service in relieving these after-pains.

"The nausea and vomiting are more relieved by the saline effervescing draught than any other remedy. Cold drinks do not seem to be more prejudicial than warm, and when much desired by the patient, should be given freely. Lemonade iced has often been taken with advantage, and even the lower orders have drank their quaffs as usual, and with seeming benefit.

"The nitric acid may be given here also with great benefit as a common drink. Fifty drops of the diluted acid added to a pint of water, sweetened to the taste, is a grateful beverage.

Choral (derived from *chorus*); a term applied to vocal music, consisting of a combination of different melodies, and intended to be performed by a plurality of singers to each part; as *choral anthem, choral service*. In Germany, this term is applied to the music of hymns, in the composition of which the Germans are so much distinguished.

Chord, in *Music*; a combination of two or more sounds according to the laws of harmony. The word

chord is often used in counterpoint; as *fundamental chord, accidental, anomalous,* or *equi vocal, transient chord.*

CHOREGRAPHY; an invention of modern times; the art of representing dancing by signs, as singing is representing by notes. It points out the part to be performed by every dancer—the various motions which belong to the various parts of the music, the position of the feet, the arms, and the body, &c. The degree of swiftness with which every motion is to be performed may be thus indicated, by which all becomes as intelligible to the dancer as a piece of music to the musician. Drawings to assist the tactician, by designating the position, motion, and evolutions of troops, have also been called *choregraphical drawings.*

CHOROGRAPHY; the description of a single district, in contradistinction to *geography* (the description of the earth). The art of drawing maps of particular districts is also called *chorography.*

CHORUS, in the drama. This was, originally, a troop of singers and dancers, intended to heighten the pomp and solemnity of festivals. This, without doubt, was at first the purpose of tragedy and comedy, of which the chorus was originally the chief part, in fact, the basis. In the sequel, it is true, the chorus became only an accessory part. During the most flourishing period of Attic tragedy, the chorus was a troop of male and female personages, who, during the whole representation, were bystanders or spectators of the action, never quitting the stage. In the intervals of the action, the chorus chanted songs, which related to the subject of the performance, and were intended either to augment the impression, or to express the feeling of the audience on the course of the action. Sometimes it even took part in the performance, by observations on the conduct of the personages, by advice, consolation, exhortation, or dissuasion. It usually represented a part, generally the oldest portion of the people, where the action happened, sometimes the counsellors of the king, &c. The chorus was an indispensable part of the representation. In the beginning, it consisted of a great number of persons, sometimes as many as fifty; but the number was afterwards limited to fifteen. The exhibition of a chorus was in Athens an honourable civil charge, and was called *choragy.* The leader or chief of a chorus was called *coryphæus,* who spoke in the name of the rest, when the chorus participated in the action. Sometimes the chorus was divided into two parts, who sung alternately. The divisions of the chorus were not stationary, but moved from one side of the stage to the other; from which circumstance the names of the portions of verse which they recited, *strophe, antistrophe,* and *epode,* are derived. But it cannot be determined in what manner the chorus sung. It is probable that it was in a sort of solemn recitative, and that their melodies, if we may call them so, consisted in unisons and octaves, and were very simple. They were also accompanied by instruments, perhaps flutes. With the decline of ancient tragedy, the chorus was omitted. Some tragedians of the present age, of whom Schiller was the first (see his prologue to the *Bride of Messina*), have attempted to revive the ancient chorus.

Chorus, in music, in its general sense, denotes a composition of two, three, four, or more parts, each of which is intended to be sung by a plurality of voices. It is applied also to the performers who sing those parts. These choruses are adapted to express the joy, admiration, grief, adoration, &c., of a multitude, and sometimes produce much effect, but are very difficult for the composer.

CHROMATE OF IRON, or CHROMEISENSTEIN, is a mineral substance of very considerable interest, as affording one of the most beautiful and durable pigments in the arts. It is found disseminated in grains and imperfectly crystallized masses—occasionally in regular octoedral crystals, its primary form—of a black colour, and shining and somewhat metallic lustre. It scratches glass, is opaque, and has a specific gravity of 4.03. According to Vauquelin, that of France consists of 43 chromic acid, 34.7 oxide of iron, 20.3 alumine, silex 2. But chemists, at the present day, consider the chrome in this mineral in the state of an oxide, and not of an acid; accordingly the mineral is now more correctly denominated the *ferruginous oxide of chrome.* It is found in great abundance in Maryland, at the Bare Hills, near Baltimore, and is contained in a steatitic or serpentine rock.

CHROMATIC, in *Music;* one of the three ancient genera—diatonic, chromatic, and enharmonic. The word *chromatic* has been adopted, as it is believed, because the Greeks were in the habit of designating this genus by characters of various colours, or, as some say, because the chromatic genus is a mean between the other two, as colour is a mean between white and black (this seems to be a very poor explanation); or, lastly, because the chromatic genus, by its semitones, varies and embellishes the diatonic, thus producing an effect similar to that of colouring. In modern music, the word *chromatic* simply means a succession of semitones, ascending or descending. Thus the expressions *chromatic semitone* (the interval which is found between any given note and that same note raised by a sharp or lowered by a flat), *chromatic scale, chromatic modulation,* are terms in use.

CHROME; the name of a metal, which, combined with oxygen so as to be in the state of an acid, was discovered by Vauquelin, in an ore of lead from Siberia. This metal has since been found combined with iron in the United States, and at Unst, one of the Shetland isles. It appears also to be the colouring principle of the emerald and the ruby, and has received its name from its property of assuming brilliant colours in the combinations into which it enters. Chrome, which has hitherto been procured in very small quantities, owing to its powerful attraction for oxygen, may be obtained by mixing the oxide of chrome with charcoal, and exposing the mixture to the most intense heat of a smith's forge. It is brittle, of a grayish-white colour, and very infusible. Its specific gravity is 5.9. Chrome unites with oxygen in three proportions, forming two oxides and one acid. The protoxide is of a green colour, exceedingly infusible by itself, but with borax, or vitreous substances, it melts, and communicates to them a beautiful emerald-green colour. Indeed, the emerald owes its colour to this oxide. The protoxide is employed at the manufactory of Sevres, in France, to give a fine deep green to the enamel of porcelain. It is applied without a flux, and melted with the enamel. Chromic acid, however, is the most important of the compounds formed by this metal along with oxygen. It is usually prepared for chemical purposes by mixing solutions of nitrate of barytes and chromate of

potash, and digesting the chromate of baryt... is formed in dilute sulphuric acid. This ...s the barytes, and the chromic acid is procu...y evaporation, in crystals of a fine ruby-r...our. It is very soluble in water, has a sour m...ic taste, and all the characters of a strong acid. ...ombines with the alkalies, earths, and meta...oxides, forming salts, many of which have very... colours.

The alkaline chromates ar...uble and crystallizable. They are of a yello... red colour, the neutral chromates being co...nly yellow, and the bi-chromates red or dee...nge. The best known of these is the bi-chro... of potash, which is one of the most splendid... at the same time one of the most useful sa... The manner in which it is formed is as follows. Chromate of iron, or rather ferruginous oxide ... chrome, reduced to fine powder, is mixed w... half its weight of nitrate of potash, and heated ...ongly for an hour or two in crucibles. The result... masses are then repeatedly digested with wate... nd the coloured liquids, which are slightly alk..., saturated with nitic acid, and concentrated by ...poration till no more crystals of nitre can be o...ned from them. The yellow liquid being now ...side for a week or two, deposits a copious crop ...ystals, whose form is that of a four-sided prism, ...inated by octihedral summits. Their colour is an ...nse lemon-yellow, with a slight shade of orange. ... parts of water at 60° dissolves about 48 parts; ...t boiling water dissolves almost any quantity. Its ...lution in water decomposes most of the metallic ...lts; those of mercury of a fine red; copper and ...on of a reddish brown; silver, dark-red, and lead, ... a beautiful yellow colour, now much used as a ...gment under the name of *chrome yellow*. Chrome ...ellow is largely manufactured in the United States, ...t Baltimore, near which place is found one of the most remarkable deposits of ferruginous oxide of chrome in the world. The process consists in adding a solution of acetate of lead (or sugar of lead) to the rough solution of chromate of potash, from which the nitrate of potash has been just separated by crystallization. The acetate of lead is added as long as any sediment falls. The liquid is then filtered, and the yellow precipitate left on the filters dried for sale.

Chromic Acid. See Chrome.

Chronic; a term applied to diseases which are of long duration, and mostly without fever. It is used in opposition to the term *acute*, which is applied both to a pungent pain and to a disease which is attended with violent symptoms, terminates in a few days, and is attended with danger. On the other hand a *chronic* disease is slow in its progress and not so generally dangerous.

Chronometer; a time-piece of a peculiar construction, at present much employed by navigators in determining the longitude at sea. In general chronometers are much larger than common watches, and are hung in gimbals, in boxes six or eight inches square; but there are also many pocket chronometers which, externally, have all the appearance of the better sort of pocket watches, and internally differ from these only in the construction of the balance. The balance and hair-spring are the principal agents in regulating the rate of going in a common watch, being to this what the pendulum is to a common clock; and this spring in the former, like the pendulum in the latter, is subject to expansions and contractions under different degrees of heat and cold, which of course affect the speed or rate of the machine; and the methods of correcting this inaccuracy mark the difference between the watch and chronometer. These are very numerous. With British and American navigators chronometers are more common than with those of any other nation. An instrument under the name of *chronometer* is also used by musicians for the accurate measurement of time.

Chyle, or Chyme, in animal economy. In the process of digestion the food is subjected to a temperature usually above 90° of Fahrenheit. It is mixed with the gastric juice, a liquor secreted by the glands of the stomach, and is made to undergo a moderate and alternate pressure by the contraction of the stomach itself. It is thus converted into a soft, uniform mass, of a grayish colour, in which the previous texture or nature of the aliment can be no longer distinguished. The *chyme*, as this pulpy mass into which the food in the stomach is resolved is termed, passes by the pylorus into the intestinal canal, where it is mixed with the pancreatic juice and the bile, and is still exposed to the same temperature and alternating pressure. The thinner parts of it are absorbed by the slender tubes termed the *lacteals*. The liquor thus absorbed is of a white colour; it passes through the glands of the mesentery, and is at length conveyed by the thoracic duct into the blood. This part of the process is termed *chylification*, and the white liquor thus formed *chyle*. It is an opaque, milky fluid, mild to the taste. By standing for some time, one part of it coagulates; another portion is coagulated by heat.

The chyle, after mixing with the lymph conveyed by the absorbent vessels, is received into the blood, which has returned from the extreme vessels before this passes to the heart. All traces of it are very soon lost in the blood, as it mixes perfectly with that fluid. It is probable however that its nature is not immediately completely altered. The blood passing from the heart is conveyed to the lungs, where it circulates over a very extensive surface presented to the atmospheric air, with the intervention of a very thin membrane which does not prevent their mutual action.—During this circulation the blood loses a considerable quantity of carbon, part of which it is probable is derived from the imperfectly assimilated chyle, as this originating in part from vegetable matter, must contain carbon in larger proportion than even the blood itself.

Cicuta. The cicuta, or common American hemlock, is one of the most valuable and important of medicinal vegetables. It is a plant indigenous in most temperate climates, and is found commonly along walls and fences, and about old ruins and buildings. The most common form in which it is administered is the extract, which is given in pills. Of this, from 12 to 60 grains per day may be taken for a long time. It is invaluable in all chronic inflammations, and enlargements of glandular parts, as the liver, the womb, &c., tumours of which it will sometimes remove in a space of time surprisingly short. Its use may be continued, if necessary, for a long time, and it is not found to debilitate or injure the system in the manner that mercury always does when long used. Its green leaves, stirred into a soft poultice, form an excellent application for painful sores and ulcers; and the same leaves, dried and rubbed fine, make, when mixed with cerate or lard, a capital

ointment for irritable sores, with which a poultice does not agree.

Cider; a liquor made from the juice of apples. The quality of this popular beverage depends principally on the following particulars, viz.:—1. kind of fruit; 2. condition of the fruit when ground; 3. manner of grinding and pressing; 4. method of conducting the requisite fermentation, and precautions to be taken against its excess.

1. The characteristics of a good cider-apple, are, a red skin, yellow and often tough and fibrous pulp, astringency, dryness, and ripeness at the cider-making season. Mr. Knight, asserts, that, "when the rind and pulp are green, the cider will always be thin, weak, and colourless; and when these are deeply tinged with yellow, it will, however manufactured, or in whatever soil the fruit may have grown, almost always possess colour and either strength or richness." It is observed by Crocker, in his tract on *The Art of making and managing Cider*, that the most certain indications of the ripeness of apples are the fragrance of their smell, and their spontaneously dropping from the trees. When they are in this state of maturity, in a dry day, the limbs may, he says, be slightly shaked, and partly disburthened of their golden store; thus taking such apples only as are ripe, and leaving the unripe longer on the trees, that they may also acquire a due degree of maturity. Mr. Buel observes, that "the only artificial criterion employed to ascertain the quality of an apple for cider, is the specific gravity of its *must*, or unfermented juice; or the weight compared with that of water. This, says Knight, indicates, with very considerable accuracy, the strength of the future cider. Its weight and consequent value are supposed to be increased in the ratio of the increase of saccharine matter." Mr. Knight says that the strongest and most highly-flavoured cider which has been obtained from the apple, was produced from fruit growing on a shallow loam, on a limestone basis. All the writers on the subjest seem to agree that calcareous earth should form a component part of the soil of a cider orchard. Coxe says the soil which yields good wheat and clover is best for a cider orchard. Mr. Buel states, "My own observation would induce me also to prefer a dry and somewhat loose soil, in which the roots destined to furnish food for the tree and fruit may penetrate freely, and range extensively in search of nutriment."

2. *Condition of the fruit.* Fruit should be used when it has attained full maturity, and before it begins to decay. The indications of ripeness we have above stated. Each kind of apple should be manufactured separately, or, at least, those kinds only should be mixed which ripen about the same time. Mr. Buel says, "The apples should ripen on the tree, be gathered when dry, in a cleanly manner. spread in an airy, covered situation, if practicable, for a time, to induce an evaporation of aqueous matter, which will increase the strength and flavour of the liquor, and be separated from rotten fruit, and every kind of filth, before they are ground."

3. *Grinding*, &c. The apples should be reduced, by the mill, as nearly as possible to an uniform mass, in which the rind and seeds are scarcely discoverable, and the pomace should be exposed to the air. Knight ascertained by experiments, that, by exposing the reduced pulp to the operation of the atmosphere for a few hours, the specific gravity of the juice increased from 1.364 to 1.678; and, from the experiment being repeated in a closed vessel with atmospheric air, he ascertained the accession to be oxygen, which according to Lavoisier, constitutes 64 per cent. of sugar. For fine cider, he recommends that the fruit be ground and pressed imperfectly, and that the pulp be then exposed 24 hours to the air, being spread and once or twice turned, to facilitate the absorbtion of oxygen; that it be then ground again, and the expressed juice be added to it before it is again pressed.

4. *Fermentation.* The vinous fermentation commences and terminates at different periods, according to the condition and quality of the fruit, and the state of the weather. According to Knight, the best criterion to judge of the proper moment to rack off (or draw the liquor from the scum and sediment), will be the brightness of the liquor which takes place after the discharge of fixed air has ceased, and a thick crust is collected on the surface. The clear liquor should then be drawn off into another cask. If it remains bright and quiet, nothing more need be done to it till the succeeding spring; but if scum collects on the surface, it must immediately be racked off again, as this would produce bad effects if suffered to sink.

Among the precautions used to prevent excessive fermentation is *stumming*, which is fuming the cask with burning sulphur. This is done by burning a rag impregnated with sulphur in the cask in which the liquor is to be decanted, after it has been partly filled, and rolling it, so as to incorporate the liquor with the gas. A bottle of French brandy, or half a gallon of cider-brandy, added to a barrel, is likewise recommended to be added as soon as the vinous fermentation is completed.

Cinchona. See Bark.

Cinnabar; a preparation of mercury, which see.

Cipher. See Arithmetic and Numerals.

Circle; a plane figure comprehended under a single line which returns into itself, having a point in the middle, from which all the lines drawn to its circumference are equal. This point is called the *centre*, and these lines the *radii*. Although, properly speaking, it is the space included within the periphery or circumference, yet, in the popular use of the word, *circle* is frequently used for the periphery alone. From the geometrical definition of the circle, it appears that its magnitude is dependent upon the magnitude of its radius or its diameter; that is, a line which touches two points of the circumference, and passes at the same time through the centre, or, which is the same thing, a line equal to twice the length of the radius. The surface of the circle is equal to the product of the circumference and half the radius. If there existed a rational proportion, that is, a proportion to be expressed in whole numbers, of the surface of the circle to a square surface, there would be at the same time a rational proportion between the diameter and the circumference. But, from geometrical reasons, no rational proportion of the diameter to the circumference is possible; it can be expressed only by approximation. However, the proportion thus obtained is quite as accurate as is necessary for any purpose in the applied mathematics. Yet there have always been instances, and some of a very late date, of men labouring long and intensely in searching for the square equal to the surface of the circle, and who often believed that they had actually solved the problem. In the approximate proportion, if the diameter is called 1, the

circumference will be equal to 3.1415926535.... Francis Vieta obtained the proportion to this number of figures. Afterwards it was farther determined by Adrianus Romanus to 15, by Ludolphus of Cologne (often improperly called *von Keulen*) to 35 (from him it is often called the *Ludolphic number*), by Sharp to 72, by Machin to 100, by Lagny to 126, and lastly, in an Oxford manuscript it was obtained up to 156 decimals. Archimides first estimated the proportion of the diameter to the circumference to be as 7 to 22, or as 1 to 3.142.....; after him, Metius, as 113 to 355, or as 1 to 3.1415929, which is correct to 6 decimals, and sufficiently accurate for most purposes. Every circle is divided into 360 degrees, and by its arcs all angles are measured. The circle therefore is one of the most important geometrical figures, and an accurate division of it is requisite for measuring the angles under which distant objects appear (upon which surveying, astronomical observations, &c. rest) —a very desirable object, for which many prizes have been offered by learned societies.

Circular Motion. A body in motion, which is continually impelled by some power towards a fixed point out of its original direction, is obliged to describe a curvilinear path round this point. A stone, slung round by a string, moves in a circle, because it is drawn toward the hand in every point of its path. The moon moves in a circle round the earth, because it gravitates towards the earth, and is thus drawn from the rectilinear direction, which it would otherwise pursue. In such cases, the point to which the body constantly tends is called the *centre of the forces*; the force itself by which it is impelled is called the *centripetal force*; that by which it strives to fly from the centre is called the *centrifugal force*; and the motion which is produced by these two forces, the *circular motion*. All the planets in the solar system are carried round the sun, and the satellites round their planets, by these forces. (See Central Forces.) The theory of circular motion is a subject of celestial mechanics, on which Newton composed his *Principia Mathematica Philosoph. Natural.* and Laplace his *Mécanique Céleste*, &c. As the model of a concise and beautiful exposition, we recommend the article under this head in Gehler's *Dictionary of Natural Philosopby*, and the introduction to *Ferguson's Lectures*.

Circular Saws, which revolve upon an axis, are preferable to straight saws, because they act continually in the same direction, and no force is lost by a backward stroke. At the same time, they can work with greater velocity, and therefore, cut more smoothly. Their size, however, is limited, because they waver and bend out of the proper plane if made too large, and if they were made so as not to waver, they would be too thick. Slitting of timber, therefore, is not often performed with them, but they are much used for cutting thin layers of mahogany for veneering, for in this case, the saw can be sufficiently strengthened towards the centre. Great velocity increases much the steadiness of a circular saw.

Circulating Medium. The expression *circulating medium* is now much more frequently used than formerly. It means the medium of exchanges, or purchases and sales, whether this medium be gold or silver coin, paper, or any other article, as oxen, tobacco, iron, slaves, usually employed in any place as the measure of the values of other articles, and is thus of a more comprehensive signification than the term *money*, which, though it applies to gold and silver coin, paper currency, and some other of the various articles used for the above purpose, does not comprehend them all, since oxen, which have by some nations, at some periods, been adopted as the measure of the comparative values of articles of commerce, would hardly be considered as coming under the denomination of *money*. It is hardly possible to imagine a people to be without a circulating medium of some description; and accordingly, we find all the tribes of savages hitherto discovered referring to some article in estimating the value of the various commodities which compose their capital. Captain Franklin says, the Krees Indians use beaver skins as their medium, and estimate the value of things by a certain number of their skins. The people of Virginia in the earlier periods of their colonial history estimated value by pounds of tobacco. In some parts of Africa, a species of small shells, cowries, are the medium of exchanges. But from the earliest times, the precious metals, where they could be had, have been preferred for this purpose, because their weight, fineness, and consequent value, could be more accurately ascertained than those of any other article, and thus comprise a sufficient value in a small compass and weight to be a convenient medium.

Many species of precious stones comprise a greater value in the same bulk and weight than either gold or silver, but their value cannot be so precisely estimated, nor are they found in sufficient quantities. Platina would be as convenient a medium as either gold or silver, provided it should continue to retain its present value; but it has not as yet been produced in sufficient abundance. It is one essential quality of a circulating medium, that it should have an intrinsic marketable value. Gold and silver for instance, besides answering as a medium, have as positive a market value as iron, tin, leather, or corn. This value is derived from their utility in the useful and ornamental arts; and it may be more precisely ascertained than the value of most other articles, since an agreement for a certain number of beaver skins, a certain quantity of tobacco, and still more for a certain number of cattle, admits of some doubt and dispute as to the quality; but an agreement for a certain weight of gold, of given fineness, admits of no dispute; it can be reduced to the utmost certainty. But we see other kinds of currency, which apparently answer the purpose of a circulating medium, and which have very little value. A small piece of paper, not worth intrinsically one penny, passes for many thousand pounds; and this sometimes leads people into the mistaken notion that intrinsic value is not an essential quality in the public currency. But we must look at what is printed or written on this paper, to learn why it passes for currency. It bears a promise that the holder shall be entitled to a certain number of pounds; of course, a certain quantity of gold and silver of a certain fineness. If this promise is valid, and will be kept, then the real medium is gold and silver, though this gold and silver may be locked up in a bank. But it may be said, that there is not, in the banks, where bank paper circulates, and perhaps not in the community, more than one pound in silver or gold for four pounds promised in the paper in circulation. How then can four pounds of paper be redeemed by one of silver? This is very easy. One holder of a

paper pound demands the silver at the bank, and passes it off, or keeps it in his purse. Now if the bank can induce this person, or the one to whom he passes the pound, to let them have it again, that is, to loan it to them, or to take something in exchange for it, they can then, with the same silver pound, redeem the second paper one, and so on. Thus a bank that has capital and a good credit, will be always able to reclaim and use the same specie successively to redeem its paper, and if it be skilfully conducted, it will always be able to command it as fast as its bills can be collected and presented for payment. A community, therefore, which only uses specie and redeemable paper as currency, has, to all practical purposes, a specie medium. The paper is, in short, so much specie for all practical purposes, for it will command gold and silver. Here then is evidently an advantage gained; for if a bank, by putting one pound in its vaults, can loan out four pounds on interest, it makes a great income on its capital, while the community loses nothing, but gains rather; for this paper is much more convenient for transportation, and equally convenient in all other respects.

It is a great object in every community to gain this advantage, arising from multiplication of money. Individuals, if not prohibited by the laws, will soon issue their paper money, and many of them make promises of paying pounds which they cannot fulfil, and thus the public be defrauded. On the other hand, the government often makes the bubble by the issue of paper money, or promises of payment never to be fulfilled.

There has rarely, if ever, been an instance of a government issuing paper money, and redeeming it punctually, and to its full nominal amount. Innumerable issues of this sort of circulating medium were made by the American colonies before the establishment of the independence of the United States; and during the war of independence, the country was inundated with what was called *continental money*, which was never redeemed.

Russia and Austria have this species of currency in circulation, always depreciated, as is usual with such money. Formerly, the sovereigns of Europe had a practice of debasing the current coin, when they wished to levy a tax in disguise, so as to make the copper with which they alloyed the silver, pass as of the value of silver. But in modern times, instead of debasing the coin, the usual resort is to a government bank or to government paper.

Government paper, issued as the ordinary currency, usually proves to be a bubble. And it may be taken for a general rule, that no currency is safe which is not of an intrinsic value, or is not based upon capital sacredly pledged to its redemption. The question then recurs, why the government may not pledge a certain amount of capital for the redemption of its paper. The reason is, that this capital must be managed, and a vast deal of skill and economy is requisite in managing a redeemable paper currency; and of all managers, the agents of a government are the least thrifty and economical. Besides, the government will ruin the credit of its own paper by excessive issues in its exigencies in times of war, when the effects of a destruction of its credit are the most disastrous. The government, therefore, ought never to trust itself to be a banker, or to issue paper money, except in desperate circumstances or pressing exigences, when no other measure can be resorted to, and when what would otherwise be wrong and dishonest, is excused for the sake of preventing the greatest national calamities. If, then, neither the government nor individuals can safely supply a circulating medium of promises, what system can be safely adopted, which shall afford all the advantages of a multiplication, in effect, of the medium of intrinsic value, namely, the gold and silver? ' Undoubtedly the system of bank circulation, whereby a certain capital is sacredly pledged to the redemption of the promises of payment of money made in the circulating bills. A well contrived, skilfully conducted system of banking, connected with one of circulation, is one of the greatest triumphs of national economy. The interest, as well as the reputation of individuals, is thus pledged in support of the system, and in furtherance of the general industry and prosperity. But shall individuals reap all the advantages of the practical multiplication of capital in consequence of supplying a currency based upon, but not consisting exclusively of specie? By no means. The government may indirectly reap greater advantages from this system than they possibly can from an attempt at becoming themselves bankers for the community, by sharing the profits with those who actually conduct the business. It is one of the proper and most important functions of the government to regulate the currency. It is bound to interfere, with proper restrictions, for preventing the frauds and bubbles to which individual enterprise and speculation inevitably lead if let loose in the career of credit; and it has a profit in so doing, by reaping some of the advantages of a bank circulation, and thus gaining an income without in fact levying a tax. As long as the government does not bear oppressively upon this species of monopoly, by attempting to levy an excessive tax for the privilege, and thus discouraging it, a liberal income may be derived from the substitution of promises on paper, for the ordinary purposes of circulation and exchange, and at the same time, such guarantees may be provided as to prevent abuse and fraud, and render this currency as safe as that of specie. We have hitherto spoken of the subject generally under MONEY; we purpose especially examining our own medium of circulation.

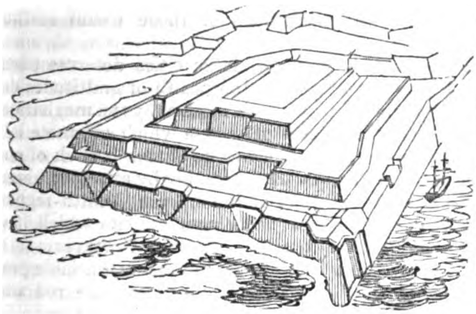
CIRCULATION OF THE BLOOD. See ANATOMY and HEART.

CIRCUMVALLATON, or LINE OF CIRCUMVALLATION, in military affairs, implies a fortification of earth, consisting of a parapet and trench, made round the town intended to be besieged, when any molestation is apprehended from parties of the enemy which may march to relieve the place.

CITADEL, or CITTADEL (a diminutive of the Italian *città*, city; signifying *little city*), in fortification; a kind of fort, consisting of four, five, or six sides, with bastions, commonly joined to towns, and sometimes erected on commanding eminences within them. It is distinguished from a castle by having bastions.

An example of the military importance of a scientifically erected citadel has lately been adduced in the protracted resistance made by General Chassé in the works of Antwerp; an account of which will be found in the SECOND DIVISION of our work, under that article. We now give an example of one of the strongest citadels in the world—we mean that which

protects the harbour and city of La Valette, in Malta. It was planned by the knights, during their powerful military sway in that island; and, if properly defended, may be said to bid defiance to any attacking force.



Cities, *Medical Statistics of*. It is well known that, in any given country, the deaths in a city are more numerous than those in the rural districts. This difference is principally felt in the first five years of life, when many more die in London than in the country. From 5 years of age to 20, the deaths in London are fewer. Between 20 and 50, many more die in London, on account of the large annual influx from the country. In all cities, a large portion of disease and death is to be assigned to the constant importation from the country of individuals who have attained to maturity, but having been previously habituated to frequent exercise in a free atmosphere and to a simple, regular diet, are gradually sacrificed to confined air, sedentary habits, or a capricious and over-stimulating diet. These causes are not equally fatal to those who have passed their early years within the walls of a city; and after the age of 50 the proportion of deaths in London is smaller than in the country. Jenner and Dr. Baron have made some curious experiments on animals, which indicate that a loss of their open range and natural nourishment has with them also a tendency to disorganize and to destroy.

Dr. Baron placed a family of young rabbits in a confined situation, and fed them with coarse green food, such as cabbage and grass. They were perfectly healthy when put up. In about a month one of them died. The primary step of disorganization was evinced in a number of transparent vesicles studded over the external surface of its liver. In another, which died nine days after, the disease had advanced to the formation of tubercles on the liver. The liver of a third, which died four days later still, had nearly lost its true structure, so universally was it pervaded with tubercles. Two days subsequently a fourth died. A considerable number of hydatids were attached to the lower surface of the liver. At this time Dr. Baron removed three young rabbits from the place where their companions had died to another situation, dry and clean, and to their proper and accustomed food. The lives of these remaining three were obviously saved by this change. He obtained similar results from experiments of the same nature performed on other animals.

In *Glasgow* the average annual mortality is about 1 in 44 persons.

In *Paris* the poor and the rich occupy the two extremities of the scale. The mortality in the one is nearly double that in the other. The average is 1 in 32. The number of violent deaths in 1823 was 690, of which 390 were cases of suicide. Reviewing, on one side, the great political, moral, and physical events which have occurred at Paris during a succession of years, and, on the other, the progress of its population, Villerme has ascertained, that whenever the people have suffered from any cause, the deaths have correspondingly increased, the births have decreased, and the mean duration of life has been shortened. In periods of prosperity, he has found results directly opposite to these. The mean duration of life in Paris is 32 years and some months It was formerly estimated that one-third of the inhabitants of Paris died in the hospitals; but Dupin has lately calculated that half the deaths in Paris take place in the hospitals and other asylums of charity. Not a fourth part of the inhabitants are buried at private cost.

In *Geneva*, the average mortality for the four years ending in 1823, was 1 in 43, which is a greater mortality than in some of the largest manufacturing towns, as Manchester and Birmingham.

It is curious that the burials exceed the births in the Russian capital, by 134 to 100. The Russians attempt to explain this by the annual influx of persons from the provinces. But this influx is not peculiar to St. Petersburg. The last-mentioned city and Stockholm are the only known metropolitan cities which present the preponderance of death over production. The annual mortality of the Russian capital is 1 in 37.

Berlin. From 1747 to 1755, the annual mortality of Berlin was 1 in 28. Between 1756 and 1799, it improved to 1 in $29\frac{1}{11}$. Here the beneficial change was retarded by the ravages, the losses, the disappointments of war, and, from 1802 to 1806, it had retrograded to 1 in 27; but from 1816 to 1822, a period of exultation and tranquillity to the Prussians, the value of life took a remarkable leap, and the annual deaths fell to less than 1 in 34.

Vienna. In the middle of the last century, the mortality of Vienna was 1 in 20, and it has not improved in proportion as other cities of Europe. According to the most recent calculations, it is, even now, as 1 in $22\frac{1}{2}$. Among 10,530 deaths, scarcely 38 persons are found to have attained the age of 90. The spirit of excessive regulation, the dread of novelty, the restrictions imposed on the medical profession, and political causes which need not be enumerated, appear to have retarded the natural progress of this city. The overweening paternity of the government interferes with the trivial concerns of the citizens, in the same manner in which an arbitrary and untaught father sometimes restrains the useful impulses of his children, while he permits an easy vent to their baser propensities.

Prague, the capital of Bohemia, has only one-third the population of Vienna, and is much healthier. The superior longevity of the Jews is strongly marked in this city. One death is annually observed among 26 of the Israelites, and 1 in $22\frac{1}{2}$ among the Christians. Instances of considerable longevity, especially among the women, are not rare. Contrary to the usual observation, longevity is confined to poverty and married life. According to an average of several years, no nobleman, no wealthy person, no bachelor, and no unmarried woman, has passed the age of 95. This is an interesting fact, but it is an extreme and

an insulated one, and does not militate against the general conservative tendency of prosperity, which a variety of evidence seems to establish.

Palermo. Mortality is here 1 in 31. January, October, and November, are the most fatal months; April, May, and June, the most healthy.

Leghorn. The average annual mortality here is 1 in 35. Among the Protestants and Jews, it is only 1 in 48, which is attributed to their greater affluence.

Rome. From a recently discovered fragment of Cicero (*De Republica*), an intimation is conveyed that the neighbourhood of Rome has been always unhealthy. Speaking of the choice of situation made by Romulus, he observes—*locum delegit in regione pestilente salubrem.* The population appears to have been gradually decreasing till the last peace, which has greatly revived it. In 1800, there were 150,000 souls; in 1810, only 123,000. Within a few years, it has gained 10,000. The annual mortality is about 1 in 25. There can be little doubt that the force of the aguish disposition of Rome might be considerably weakened by steady and well-directed efforts, supported by a proportionate capital; but it is to be feared that such a combination of circumstances will not readily meet at Rome. In 1816, 17 out of the 22 French students were attacked with intermittent fevers. The Villa Medici, in which they reside, was formerly healthy; but water, brought at a great expense, to embellish the garden, had been suffered to stagnate there.

Naples. The annual mortality here is 1 in 23; a fact that one would not have expected in such a delightful situation, compared with pestilential Rome, where the mortality is less. The population of Naples is nearly three times that of the ancient mistress of the world.

Brussels. The average mortality is very great, being 1 in 26.

Amsterdam. The population of this once great city is decreased, in consequence of declining commerce and political changes. And it is not a little curious, as well as melancholy, to observe that its mortality has increased with the progress of decay. In 1777, the ratio of mortality was 1 in 27—a period when Amsterdam was one of the healthiest as well as one of the most flourishing cities of Europe. The deaths have now increased to 1 in 24, and Amsterdam is one of the least healthy as well as least prosperous seaports of Europe. A decree was some time back issued, that after the 1st of January, 1829, no burials shall be permitted in towns or churches throughout North Holland.

Stockholm. Drunkenness appears here, as at Berlin, to produce a large share of the mortality. In a recent year, this city exhibited a singular instance of an excess of 1439 more deaths than births—a symptom which it is painful to observe in a brave and industrious people. This disproportion existed particularly amongst the garrison, and is ascribed to the immoderate use of brandy.

The Editor of the present work fully coincides in the opinion here expressed by the intelligent writer of this article. Spirituous liquors have been the fruitful source of bodily, as well as moral disease in every country in which the government has so far forgot its duty, as to pander to the vices of the people, for the mercenary consideration of a slight increase of revenue. In America, where this degrading vice was once so prevalent, spirituous liquors are now but little seen, and in their navy, a service which was formerly considered as the very "hot-bed of drunkenness," the habitual use of spirits is rapidly passing away. Our trans-atlantic brethren have accomplished this moral wonder mainly by the aid of *temperance societies*, and we shall certainly, under that head, point out the mechanism of those useful institutions.

The medical police of large cities deserves particular attention, because the health of multitudes depends upon the care which is taken by the magistrates to remove the causes of disease which originate in a great population. Knowledge of this branch of medical science can be obtained only by attentive observation, and the study of the different health-regulations of large cities under governments which have paid particular attention to it. See CLIMATE.

CITRIC ACID. This acid exists in variable proportions in the lemon, orange, and the red acid fruits. This acid is white, crystallizes in rhomboidal prisms, unalterable in the air, inodorous, of a very acid taste. Specific gravity, 1.034 According to Messrs. Gay-Lussac and Thénard, it is composed of carbon, 33.81, oxygen, 59,859, and hydrogen, 6.330. Heated, it is decomposed, and is partly changed into a new acid, called *pyro-citric*. It is very soluble in boiling water, and in three-fourths of its weight of cold water. Alcohol dissolves a smaller proportion. The aqueous solution, concentrated in a small degree, is easily altered on exposure to the air. It is obtained by saturating the lemon-juice with pulverized chalk, and treating the insoluble citrate which is formed, by diluted sulphuric acid. It is employed instead of lemon-juice for making lemonade, and it acts then like the other refrigerant medicines. In large doses, and concentrated, it might produce serious accidents, on account of its caustic action.

CLARET. See WINES.

CLARICHORD, or CLAVICHORD; a keyed instrument, now out of use, somewhat in the form of a spinet, and the strings of which are supported by five bridges. One distinction in the clarichord is, that the strings are covered with pieces of cloth, which render the sound sweeter, and at the same time deaden it so as to prevent its being heard at any considerable distance. On this account, it was formerly much used by the nuns, who could practise on it without disturbing the dormitory. It is sometimes called the *dumb spinet*.

CLARIFICATION, or the separation of the insoluble particles that prevent a liquid from being transparent, may be performed by *depuration, filtration*, or *coagulation*. In the first of these operations, the liquid is permitted to subside, without being in the least disturbed, until all the particles which were in suspension are precipitated; it is then decanted. This mode of clarification can only be used when the substance on which we operate is in a large quantity, or is of a nature not to be altered during the time necessary to complete this operation, and finally when its specific gravity is less than that of the particles which render it turbid. *Filtration* is a process by which a liquid is strained through a body, the interstices of which are small enough to stop the solid particles contained in it. Filters of wool, linen, paper, powdered glass, sand, or charcoal, may be used, according as the liquid is more or less dense, or of a nature to operate upon any one of these bodies. Finally, clarification by *coagulation* is per-

formed with the assistance of albumen contained in the liquid, or some is added to it for this purpose, which, by the action of caloric, of acids, &c. becomes solid, forms a mass, and precipitates the extraneous substances. The white of eggs is generally used for this purpose.

CLARINET. A wind-instrument of the reed kind, the scale of which, though it includes every semitone within its extremes, is virtually defective. Its lowest note is E below the F cliff, from which it is capable, in the hands of good performers, of ascending more than three octaves. Its powers, through this compass, are not every where equal; the player, therefore, has not a free choice in his keys, being generally confined to those of C and F, which indeed are the only keys in which the clarinet is heard to advantage. The music for this instrument is therefore usually written in those keys. There are, however, B flat clarinets, A clarinets, D clarinets, B clarinets, and G clarinets: the three latter are scarcely ever used in England.

CLAVICHORD. See CLARICHORD.

CLAVICIMBALUM; the name originally given to the harpsichord.

CLAY is a mixture of decomposed minerals, and hence it is by no means uniform in its composition. Several varieties soften in water, and allow themselves to be kneaded and formed into moulds—a property by which they are fitted for the use so commonly made of them. Some are easily fusible, others refractory; some acquire particular tints, others lose their colour and become white when exposed to a strong heat; upon all of which properties their applicability depends. They occur in beds near the surface of the earth, or covered by the soil, in the formations of brown and black coal. In the latter situation they often contain the remains of vegetables, and are called *slate clay*, which is intimately related to bituminous shale and alum-earth.

Alumine is the basis of all clays, and imparts to them their predominating characters. It is mixed with very variable proportions of silex, magnesia, lime, and oxide of iron. The varieties of clay are of various important applications in pottery, in manufacturing stone-ware and porcelain, in constructing furnaces for metallurgic operations, &c.—Some of the principal varieties are *indurated clay*, or *clay stone*, which is clay in its highest state of induration. It is soft, but not easily diffused in water, and does not form with it a ductile paste.

Porcelain clay, so named from the use to which it is applied, is white, with occasional shades of yellow and gray. It is dull and opaque; feels soft; in water it falls to powder, and when kneaded, it forms a ductile paste. It is in general infusible by any heat that can be raised. It consists essentially of silex and alumine; that of Cornwall contains 60 parts of alumine with 20 of silex.

Potter's clay and *pipe clay* are similar, but less pure, generally of a yellowish or grayish colour, from the presence of iron.—*Loam* is the same substance mixed with sand, oxide of iron, and various other foreign ingredients.—The *boles*, which are of a red or yellow colour, are of a similar composition, and appear to owe their colours to oxide of iron. They are distinguished by their conchoidal fracture.—The *ochres* are similar to the boles, containing only more oxide of iron.

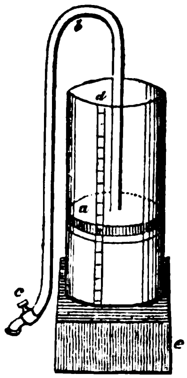
Fuller's earth has an earthy fracture, sometimes slaty, is dull and opaque. In water it falls to powder, without forming a ductile paste. It is used to remove grease from cloth.

Tripoli is found loose or indurated; its fracture is earthy; it feels harsh and dry; does not adhere to the tongue. It is used for polishing the metals and glass. The clays are too generally distributed to require the enumeration of their localities.

CLEPSYDRA; an instrument used in the measurement of time. In the earliest water-clocks, the indication of time was effected by marks corresponding to either the diminution of the fluid in the containing vessel, during the time of emptying, or to the increase of the fluid in the receiving vessel duriug its time of filling; but it was soon found that the escape of the water was much more rapid out of the containing vessel when it was full, than when it was nearly empty, owing to the difference in the pressure at different heights from the surface. This irregularity in the dropping, presented an obstacle which required much ingenuity to correct. Ctesibius of Alexandria, who flourished more than two hundred years prior to the Christian era, spent much time in devising various contrivances for perfecting the instrument. One serious objection to its practical application at that period arose from the daily inequality of the Egyptian hours. As one-twelfth part of the time that passed from sun-setting to sunrise was called an hour of the night, not only did the hours of day differ from the hours of night, but from one another, at all times, except at the vernal and autumnal equinoxes; hence, it became necessary, either to make the water fall irregularly into a receiving vessel, with equi-distant hour-marks, or to have varying hour-marks for a regular efflux; the first of these methods was thus effected. A conical hollow vessel was inverted, or placed like a funnel in a frame, there being a very small aperture at the apex of the cone, and another solid cone, every way similar as to dimensions, was plunged into the hollow one, when filled with water to a greater or smaller depth, accordingly as the efflux was wanted to be more or less rapid, and then adjusting marks, corresponding to every day and night in the year, were put on a long stem, inserted in the broad end of the solid cone, and kept in its position by the frame, to show how much the inner cone was to be depressed or elevated, to accelerate or retard the issue of the fluid for the corresponding time. A waste pipe, connected with the top of the conical vessel, carried off the superfluous water; hence the constant influx of water preserved an unvarying height at the surface from the aperture, which aperture was varied at pleasure, by the elevation or depression of the inner cone; if now we suppose the subjacent vessel to be a cube, cylinder, or any other regular figure, and equidistant hour-marks to be properly made on its side, the surface of the water, or an index borne by it on a piece of cork, would, as it rose, indicate the hours corresponding to those marks.

As an improvement, or rather appendage to this construction of the clepsydra, a bar, with rackwork at the upper end, was made to float on the surface of the lower vessel, so that as it rose in the vessel, the bar turned a small wheel, fixed to the upper part of the frame by a cock, on the arbor of which wheel a hand was put, which revolved, and indicated the hours on a fixed dial-plate.

We may now turn to a more simple form of the clepsydra. Its arrangement is shown in the engraving.



It consists of a cylinder of glass furnished with a float, *a*, supporting a syphon, *b*. If we suppose the water gradually discharged from a small stop-cock at the end of the syphon, the passage of the time will be indicated by the descent of the float past the graduated line, *d*. It will be obvious that whatever situation the float may be placed in, the pressure of the fluid in the syphon is the same, and as such it will pass through equal distances in equal times. The Editor presented an instrument of this description to the National Repository, some years ago.

Cliffs, or Claves; certain indicial characters placed at the beginning of the several staves in a composition, to determine the local names of the notes, and the sounds in the great scale which they are intended to represent. The three cliffs now in use, viz., the F, or bass cliff, the C, or tenor cliff, and the G, or treble cliff, by the several situations given them on the stave, furnish us with the means of expressing all the notes within the usual compass of execution, both in vocal and instrumental music, without a confused addition of leger lines, either above or beneath the stave.

Climate. The ancients denoted by this name the spaces between the imaginary circles, parallel to the equator, drawn in such a manner over the surface of the earth, that the longest day in each circle is half an hour longer than in the preceding. According to this division, there were twenty-four climates from the equator, where the longest day is 12 hours, to the polar circle, where it is 24 hours. From the polar circle, the longest day increases so rapidly, that only one degree nearer the pole it is a month long. The *frigid zones*, so called, that is, the regions extending from the northern and southern polar circles to the corresponding poles, some geographers have divided again into six climates. We have learned from a more accurate acquaintance with different countries, that heat or cold depends not merely on geographical latitude, but that local causes also produce great variations from the general rule, by which a region lying near the equator should always be warmer than one remote from it. By the word *climate*, therefore, we understand the character of the weather peculiar to every country, as respects heat and cold, humidity and dryness, fertility, and the alternation of the seasons. The nature of a climate is different according to the different causes which affect it, and the observations hitherto made have led, as yet, to no definite result. In general, however, geographical latitude is the principal circumstance to be taken into view in considering the climate of a country. The highest degree of heat is found under the equator, and the lowest, or the greatest degree of cold, under the poles. The temperature of the intermediate regions is various, according to their position and local circumstances.

Under the line, the heat is not uniform. In the sandy deserts of Africa, particularly on the western coast, also in Arabia and India, it is excessive. In the mountainous regions of South America, on the contrary, it is very moderate. The greatest heat in Africa is estimated at 70° of Réaumur, which is very hot. The greatest degree of cold at the poles cannot be determined, because no one has ever penetrated to them. The greatest altitude of the sun at noon, and the time of its continuance above the horizon, depends altogether on the latitude. Without regard to local circumstances, a country is warmer in proportion as the sun's altitude is greater and the day longer. The elevation of any region above the surface of the sea has likewise an important influence on the climate. But the nature of the surface is not to be disregarded. The heat increases as the soil becomes cultivated. Thus, for the last thousand years, Germany has been growing gradually warmer by the destruction of forests, the draining of lakes, and the drying up of bogs and marshes. A similar consequence of cultivation seems to be apparent in the cultivated parts of North America, particularly in the Atlantic states. The mass of minerals, which composes the highest layer of a country, has, without doubt, an influence on its temperature. Barren sands admit of a much more intense heat than loam. Meadow lands are not so warm in summer as the bare ground. The winds to which a country is most exposed by its situation, have a great influence on the climate. If north and east winds blow frequently in any region, it will be colder, the latitude being the same, than another, which is often swept by milder breezes from the south and west. The influence of the wind on the temperature of a country is very apparent in regions on the sea-coast. The difference in the extremes of temperature is least within the tropics. The heat, which would be intolerable when the sun is in the zenith, is mitigated by the rainy season, which then commences. When the sun returns to the opposite half of the torrid zone, so that its rays become less vertical, the weather is delightful. Lima and Quito, in Peru, have the finest climate of any part of the earth. The variations in temperature are greater in the temperate zones, and increase as you approach the polar circles. The heat of the higher latitudes, especially about 59° and 60°, amounts in July to 75° or 80° of Fahrenheit, and is greater than that of countries 10° nearer the equator. In Greenland, the heat in summer is so great that it melts the pitch on the vessels. At Tornea, in Lapland, where the sun's rays fall as obliquely, at the summer solstice, as they do in Germany at the equinox, the heat is sometimes equal to that of the torrid zone, because the sun is almost always above the horizon.

Under the poles, the climate is perhaps the most uniform. A greater degree of cold than any we are accustomed to, seems to reign there perpetually. Even in midsummer, when the sun does not go down for a long time (at the poles not for six months), the ice never thaws. The immense masses of it which surround the poles, feel no sensible effect from the oblique and feeble beams of the sun, and seem to increase in magnitude every year. This is very remarkable; for there is the most undoubted evidence that these now deserted countries were, in former ages, inhabited. But, within a few years, large portions of this continent (if we may so call it) of ice have separated, and floated down to southern seas. This led our government to adopt the project of penetrating to the north pole. Captains Ross and

Parry have successively sailed as far as possible into the arctic ocean.

From the general division of America into lofty mountainous *plateaus* and very low plains, there results a contrast between two climates, which, although of an extremely different nature, are in almost immediate proximity. Peru, the valley of Quito, and the city of Mexico, though situated between the tropics, owe to their elevation the general temperature of spring. They behold the *paramos*, or mountain ridges, covered with snow, which continues upon some of the summits almost the whole year, while, at the distance of a few leagues, an intense and often sickly degree of heat suffocates the inhabitants of the ports of Vera Cruz and of Guayaquil. These two climates produce each a different system of vegetation. The flora of the torrid zone forms a border to the fields and groves of Europe. Such a remarkable proximity as this cannot fail of frequently occasioning sudden changes, by the displacement of these two masses of air, so differently constituted—a general inconvenience experienced over the whole of America. Every where, however, this continent is subject to a lower degree of heat than the same latitudes in the eastern portion of the earth. Its elevation alone explains this fact, as far as regards the mountainous region; but why, it may be asked, is the same thing true of the low tracts of the country? To this the great observer, Alexander Humboldt, in his *Tableaux de la Nature*, makes the following reply: "The comparative narrowness of this continent; its elongation towards the icy poles; the ocean, whose unbroken surface is swept by the trade winds; the currents of extremely cold water which flow from the straits of Magellan to Peru; the numerous chains of mountains, abounding in the sources of rivers, and whose summits, covered with snow, rise far above the region of the clouds; the great number of immense rivers, that after innumerable curves always tend to the most distant shores; deserts, but not of sand, and consequently less susceptible of being impregnated with heat; impenetrable forests that spread over the plains of the equator, abounding in rivers, and which, in those parts of the country that are the farthest distant from mountains, and from the ocean, give rise to enormous masses of water, which are either attracted by them, or are formed during the act of vegetation,—all these causes produce, in the lower parts of America, a climate which, from its coolness and humidity, is singularly contrasted with that of Africa. To these causes alone must we ascribe that abundant vegetation, so vigorous and so rich in juices, and that thick and umbrageous foliage, which constitute the characteristic features of the new continent." To these remarks Malte-Brun adds, "Assuming this explanation as sufficient for South America and Mexico, we shall add, with regard to North America, that it scarcely extends any distance into the torrid zone, but, on the contrary, stretches, in all probability, very far into the frigid zone; and, unless the revived hope of a north-west passage be confirmed, may perhaps reach and surround the pole itself. Accordingly, the column of frozen air attached to this continent, is no where counterbalanced by a column of equatorial air. From this results an extension of the polar climate, to the very confines of the tropics; and hence winter and summer struggle for the ascendency, and the seasons change with astonishing rapidity. From all this, however, New Albion and New California are happily exempt; for, being placed beyond the reach of freezing winds, they enjoy a temperature analogous to their latitude."

A complete system of meteorology, so far as the medical properties of climates, with regard to temperature only, are concerned, presents almost as great difficulties as a complete theory of the nature and cure of diseases. In this, as in many other departments of medical knowledge, we perpetually find a multiplicity of accounts, apparently well attested, but totally at variance with each other, which render it desirable to appeal to some more satisfactory testimonials than the results of common and superficial observation; while the evidence which would be required for forming useful conclusions upon safe and scientific grounds, although in this case completely within the scope of the human faculties, is still such as to require, for its production, a combination of perseverance and accuracy, which has certainly never yet existed, and which probably can scarcely ever be expected to be found in a sufficient number of collateral observers. Any voluminous work on the subject, whether systematic or empirical, must unavoidably contain much useless, and some erroneous matter; and a short statement of a few facts, which appear to be tolerably well ascertained, first, respecting the physical character; and, secondly, respecting the medical effects of the principal climates which deserve our notice, is all that it will be possible to attempt in the present article.

The simple indications of a thermometer, however accurately they may be observed in the most unexceptionable exposure, by no means afford a correct test of the temperature as it affects the human system; nor is it possible to express the modifications produced by wind or moisture, even supposing them to be easily known, by any numerical measure which shall be applicable to every relative situation of the individual. It is known that an atmosphere at 65°, with a thick fog, and a little wind from N. E., may appear, to a person taking moderate exercise, most oppressively sultry, although a person sitting still long might have felt the same air uncomfortably cold. Moisture must make both heat and cold more sensible; the one, by diminishing perspiration; the other, by increasing the conducting power of air. Wind is doubly concerned in affecting the properties of a climate: first, as the great cause of preventing a general accumulation of heat over considerable tracts of country; and secondly, as having a similar effect with respect to the immediate neighbourhood of the person; and its operation is as generally perceptible in the latter way, where we have no precise mode of estimating its magnitude, as in the former, where it is correctly indicated by a thermometer sufficiently exposed: although in fact, the most shaded fixed thermometer may often be observed to indicate a temperature many degrees higher than that of the breeze which is circulating in the neighbouring country. Still more commonly by the sea-side the wind exhibits the temperature of the water over which it has blown. At Worthing, it is seldom above 64° in the hottest weather, although the sea, when the tide flows in at noon, over the heated expanse of sand, is sometimes raised to 78°, where it is several feet deep.

To the inhabitants of these islands, the most important properties of the climates of other countries

are those which render them more or less fit for the residence of persons liable to catarrhal, or consumptive affections. Hence, warmth and equability of temperature, especially in the winter months, are the first objects of our inquiry in the theoretical comparison of climates. Moisture is supposed by some to be favourable; by others, to be unfavourable to such persons: it may, therefore, be safely neglected, except as tending to increase the evils depending on a want of equability of temperature. The effluvia of moist ground are sufficiently well known as the causes of paludal fevers; farther than this they require no particular investigation. Nor can we attempt to assign any reason for peculiarities which render some situations preferable to others, for some individuals only labouring under a given disease, as asthma, which is sometimes induced by the atmosphere of cities, and sometimes of the country; and which is occasionally mitigated by a residence in places having no marked distinctions from such as are less favourable to it, as Kensington, and perhaps some others.

In the hotter seasons there are few diseases, and few constitutions which would require a climate milder than our own: in the colder, an increase of the facility of circulation which heat appears to afford, may often be beneficial; partly perhaps, as exciting perspiration, and partly as preventing too great a congestion of blood in the internal parts of the body. The mean temperature of the six winter months is therefore the first point of comparison that requires our attention; and such a comparison may easily be derived from the registers which are usually kept in circumstances nearly similar.

Paris	36.8

It appears from this comparison that none of the situations here enumerated north of Lisbon, except Penzance, has any material advantage over London in the mildness of its winter. The best parts of Devonshire seem to be about a degree and a half warmer; Torbay, however, may perhaps be a little milder than this. The account which was kept at Ilfracombe, must have been taken from a thermometer in a confined, or a sunny situation. But Penzance may be fairly considered as having a temperature 4½° higher than London in the coldest months; nor is the journal here employed the only one which allots such a superiority to the climate of this extremity of our island. It is remarkable that the temperature of the three coldest months is the same at Paris as at Edinburgh, being in both these cities about three degrees lower than in London. There are probably particular spots on the coast of Hampshire or Sussex, which, from their sheltered situation, must be considerably less subject to the effect of the northern and eastern winds than most other parts of the island; and Hastings, or its neighbourhood, may perhaps be reckoned among the most eligible of these; but the farther we go up the channel, the more remote we become from the mild gales of the Atlantic, while the prevalent south-westerly winds, in passing over a considerable part of the continent, must have lost much of their warmth. It is scarcely necessary to observe, that both Malta and Madeira present, numerically, a mean temperature for the winter months as favourable for an invalid as can possibly be desired.

Equability of temperature is a second quality, of no small importance, as tending to diminish the chance of incurring, or aggravating pulmonary diseases, by repeatedly taking cold. When indeed the temperature is much below 60°, the most material changes are those which occur upon going from the house into the open air; so that a cold climate becomes, in some degree, of necessity a changeable one also. The regularity of this change, and the power of avoiding its effects by additional clothing, as well as of obviating them in some measure by exercise, contribute however to lesson its influence: and it does not, therefore, altogether supersede the effects of that changeableness which consists in a great extent of variation of the temperature of two successive days, or of different hours in the course of the same day. The simplest, and perhaps the best mode of appreciating the effect of the extent of such a variation in deteriorating a climate, is to observe for each month, the greatest variation at the same hour, in any two successive days within its duration. The mean variation of successive days may also be computed, in order to assist in the comparison; and the mean diurnal range, or the space through which the surface of the mercury moves, in ascending or descending, throughout the day and night, will give a collateral estimate of a similar nature. The best practical mode of deducing this range from the observations is, to find separately the mean of the heights for the morning and afternoon, and to double their difference. Where none of these principles can be obtained, the extreme variation of each

month will afford a character not altogether unimportant.

Mean of the greatest Variations of successive Days in each Month, for the Winter Months.

Sidmouth, 1811, January to March	34.
Clifton, 1803, February and March (Lond. 36°.)	31.

It does not appear that Devonshire possesses any decided advantages over London with respect to equability of climate, if we judge of the climate of London from the observations made at the apartments of the Royal Society only; but in so central a situation, the change must be rendered much less sensible by the effect of the surrounding buildings; and they appear to be considerably greater at Gravesend, and greater still at Knightsbridge In this respect, too, Penzance retains its superiority even over Devonshire. Lisbon seems to have a less variable temperature than any part of Great Britain; and in Madeira, to judge by the monthly variation only, the advantage in this respect appears to be still greater; on this account it is much resorted to.

The greatest possible equability of temperature seems, however, to be obtained in a sea voyage to a warm climate, in which the variation seldom amounts to half as much as in the most favourable situation on shore, even on a small island; and in pulmonary cases, the motion of a ship would probably in general be rather beneficial than otherwise, while the fatigue of travelling in bad roads, and the danger of sleeping in damp beds, present an alternative by no means favourable to a journey by land.

The direction of the wind alone can seldom have an immediate effect on the salubrity of the climate, except by variously modifying its temperature, according to the seas or countries over which it blows. There is a method of computing the mean direction of the wind, which does not appear to have been hitherto adopted, but which affords a very simple and intelligible result, although somewhat laborious if extensively applied. It consists in finding the bearing and distance of a point, to which a light body would be carried by the wind in the course of the year, supposing the velocity to be constant, when its variations have not been ascertained by observation. It is obvious that the bearing of such a point will show at once the mean direction of the prevalent winds; and its distance, compared with the effect of a constant wind for the same time, as a unit, will indicate the degree in which those winds have prevailed.

Prevalence of Winds.

London, 1790-4	W. 9° S.	.234
London, 1794,	W. 33° S.	.188
Dawlish, 1794,	W. 6° S.	.466
Lisbon, 1788,	N. 1° W.	.315

According to this comparison, it appears that the mean direction of the wind in Devonshire is somewhat more westerly than in London; and that the degree in which such westerly winds predominate, is more than twice as great as in London; or, if we convert the measure into days, that the predominance amounted in 1794, to sixty-eight days for London, of a wind nearly west-south-west, and to one hundred and seventy days for Dawlish, of a wind a little to the south of west.

The variations of the climate of the same place, with respect to mean temperature, are easily collected from the usual meteorological computations. Dr. Heberden has very successfully combated the common opinion respecting the superior salubrity of cold winters; it appears, however, that the winter which he particularly observed was more variable, as well as colder, than usual. Mr. Kirwan has attempted to account for the greater frequency of colds, which he supposes to occur in spring and in autumn, by the greater variability of the temperature at those seasons: but both the fact and the explanation are very questionable; for in reality the variations of temperature, if estimated by the total range of the thermometer within the twenty-four hours, are almost uniformly greatest in the hottest weather. In London, the greatest variations of successive days at the same hours in the morning are greatest in winter; in the afternoon, in summer; and although the latter are a little greater in April than in some of the succeeding months, the difference is by no means considerable.

Of the empirical evidence which may be collected respecting the medical effects of different climates, the most authentic is perhaps that which is derived from well regulated bills of mortality; since these documents ought to afford us a tolerable criterion of the general healthiness or unhealthiness of a place. Thus, in Stockholm, the annual deaths amount to $\frac{1}{19}$ of the population, in London to $\frac{1}{21}$, in the Pays de Vaud to $\frac{1}{45}$, and in some villages in different parts of Great Britain to $\frac{1}{80}$ only, we cannot hesitate to consider a residence in the country as generally more healthy than in a metropolis similar to either of those cities; although it cannot fairly be concluded that the healthiness is precisely in the proportion which might be inferred from this composition, until we have considered how far the effect of emigration to a great town may influence the apparent mortality.

After the age of eight or ten, the probable duration of life may be estimated with sufficient accuracy, as Demoivre has very ingeniously shown, by assuming that, of a certain number of persons born together, one will die annually until the whole number is become extinct; and it is well known, that this number may in common cases be eighty-six; so that at any given age, for instance, thirty-six, we may find the probable duration of life by deducting it from eighty-six, and halving the remainder, which will give us twenty-five for the estimate required; and if this law were universally true from the time of birth, it is easy to show that the mortality in a metropolis would always be increased by the accession of settlers; so that if, for example, the whole population were supplied by settlers at twenty, and all children were sent to a neighbouring village to be educated, the mortality of the town, instead of $\frac{1}{43}$, would become $1 : (43-10) = \frac{1}{33}$, and that of the village would be $1 : (86-10) = \frac{1}{76}$; and that any partial changes of a similar nature would cause a smaller alteration of the apparent salubrity, in proportion to their extent. But the mortality during infancy is actually much greater than is assumed in the simple hypothesis of Demoivre; and from this circumstance, as well as from the frequent return of aged persons into the country, Dr. Price has inferred that emigration in general has no tendency to increase the mortality of cities. In reality, the question depends altogether upon the mortality which might be supposed to take place within the first year, which is often estimated at one-third of the births; but nothing like this can well be expected to occur at any tolerably healthy place in the country; and on the whole it does not appear that Dr. Price's observations can by any means be admitted as conclusive. With respect to the evidence afforded by the prevalence of diseases, it has been observed by Dr. Gregory, that removing from a colder to a warmer climate may be beneficial, even in those diseases to which the inhabitants of the warmer climate are subject; but if they appeared to be equally or more subject to any disease than the inhabitants of the colder, there would surely be little encouragement for the change: for instance, in a person supposed to be liable to diseases of the liver, it would surely be injudicious to undertake a voyage to a hot climate, with a view of avoiding the chance of taking cold, since the well-known frequency of hepatitis in such climates, would much more than counterbalance any prospect of advantage from the change.

The frequency of consumptions is decidedly greater in cold than in hot climates, but not by any means in exact proportion to the depression of the mean temperature. The principal situations that require to be compared with the metropolis as a standard, are the south of England, south of Europe, the islands of the Mediterranean, Madeira, and the West Indies.

There do not appear to be any precise accounts of the proportionate mortality from consumption at any place upon the southern coasts of this island, on a scale sufficiently extensive for the comparison; but there is abundant reason to think that such a report would be greatly in favour of the salubrity of these coasts, more so indeed than any conclusions that we should be at all authorized to form from such thermometrical observations as have hitherto been compared. A greater number of registers is still wanting to obtain sufficient evidence for the inquiry: and it would be desirable that some journal should be kept at one of the Scilly islands, as a situation fully exposed to the influence of the sea air; for there can be little doubt that, for equability of temperature, a very small island must have great advantages above every other situation on shore. But in the present state of our knowledge on this subject, although we are fully justified in recommending a residence in Devonshire or Cornwall as advisable in a certain stage of consumption, it does not appear that any meteorological observation will authorize us to represent the advantages to be gained by such a residence, as by any means equivalent to those which may be found in remoter situations; nor that the empirical testimony derived from accounts of the comparative prevalence of the disease, is at all so clear, or so firmly established, as to make up for the want of evidence of a great and decided superiority of the climate.

In the south of Europe, the situations which have been most frequented are Lisbon, or some other part of the peninsula, the neighbourhood of Montpelier, and different parts of Italy. In Spain, and probably in Portugal, consumption is said to be not common, but by no means wholly unknown; and whether from accident, or from causes which are likely to have a constant operation, the climate of Portugal has certainly failed, in a number of instances, of producing any material benefit, where there has been apparently a very fair chance for the patient's recovery. With respect to the south of France, it is perhaps sufficient to remark, that the general proportion of deaths from consumption at Marseilles, is fully as great as the greatest which has been observed in London, where, according to Dr. Heberden's remark, its prevalence has of late years been so much increased. In Italy, the disease appears to be decidedly less frequent; and there is no reason to doubt but that in the southern parts of that country there may be situations approaching in their climates to those of the neighbouring islands.

It is, however, highly probable that some of these islands possess very considerable advantages over almost every part of the continent which surrounds them, at least as far as we can judge by their affording a climate of that description which seems to be the most desirable; for actual experience will not allow us to be too confident of obtaining success, even from a residence in these. Dr. Domeier informs us, in his very interesting account of the island of Malta, that the thermometer seldom varies here more than 6° in the twenty-four hours, or stands below 51°, even in the depth of winter; while in Lisbon he has seen ice, and both ice and snow in Naples; besides that, in these two cities the difference between day and night often amounts to 20°. If an invalid leaves England in the middle of August, the voyage lasts about a month, and is often of itself highly beneficial, so that he arrives at Malta in time to be fully prepared to be farther benefited by the mild winter. It appears, however, from the more particular account which Dr. Domeier elsewhere gives of the temperature, that it continues throughout October rather higher than is altogether desirable, being seldom below 70° throughout that month; and in a country where there is scarcely any visible foliage, walls occupying universally the place of hedges, this cannot be a matter of perfect indifference.

In Madeira, though the thermometer attached to a building is seldom found below 54°, there are frequently cold winds, snow, or more commonly something intermediate between snow and hail, often falling on the mountains at the height of one thousand feet above the sea, and at still greater elevations sometimes lying undissolved till July: and this imperfect kind of hail falls occasionally even on the low grounds. The island is probably a more agreeable residence than Malta; but it seems very doubtful whether it possesses any determinate advantage over it with respect to climate; and it is not impossible, that some other islands in its neighbourhood may afford a greater equability of temperature. We have, however, a more established experience of its beneficial effects in pulmonary diseases than of almost any other situation. Dr. Adams says, that "in cases of tubercular or scrofulous consumption, if the patient does not saunter away his time after you have advised him to leave England, we can with certainty promise a cure." (*Med. Phy. Journ.* April, 1800.) The true English consumption he thinks is not to be found in Madeira, while the catarrhal affection, which somewhat resembles it, though without purulent expectoration, is not uncommon, and may be fatal if neglected or improperly treated. Dr. Gourlay agrees with Dr. Adams, in his report of the general benefit derived from the climate of Madeira, by consumptive persons going to it from colder countries to pass the winter in the island, and of the frequency of catarrhal affections among the inhabitants; but he strongly insists that genuine consumption is also very common and very fatal. There can however be little doubt, from the concurrent testimony of the majority of the observers, that the climate of Madeira is extremely salubrious, and that consumptions, though they may sometimes occur, are comparatively rare.

In the West Indies, it is agreed by all authors, that consumptive affections are almost unknown, and that scrofula in all its forms is uncommon; while the inhabitants of the West Indies, coming into a colder climate, are peculiarly liable to the attacks of these diseases. Dr. Hunter, however, observes, that notwithstanding this exemption in favour of the natives of the West Indies, a residence in this climate appeared to him to be of no manner of advantage to persons who were already affected by incipient consumptions when they arrived there. We cannot doubt the accuracy of this evidence, as far as regards the facts which came immediately under Dr. Hunter's observation; they principally related to the military, who perhaps laboured under some peculiar disadvantages: but other practitioners have given much more favourable reports of the events of cases, in which they have made trial of the effect of a residence in this climate; and if we may be allowed to draw any inference from the qualities of a climate, as indicated either by the thermometer, or by its effects on the constitutions of the inhabitants, there can be little doubt that a residence in Bermudas, in a temperate and sheltered part of Jamaica, or in some other of the West India islands, together with the equable qualities of the sea air, to which the patient must be exposed during the voyage, must present every advantage towards the recovery of a consumptive person that climate alone can possibly bestow.

In other diseases, the effects of climate are perhaps less exclusively beneficial, although it appears that gouty persons often derive considerable benefit from a residence in the hottest countries, as in the East Indies, or at Ceylon in particular. Dr. Gregory seems to be persuaded that life may be lengthened, and the inconveniencies of old age retarded or mitigated, by repeated emigrations into warmer and warmer climates, after the age of fifty or sixty, according to circumstances: and he thinks that even posterity may be benefited by an emigration of this kind.

In whatever situation the residence of an invalid may be fixed, it is of no small importance that the aspect and exposure of the house which he occupies, should be selected with a view to the qualities of climate which he is desirous of obtaining. We have an illustration of the truth of this remark, in an observation recorded by Dr. Carrick, respecting the influenza of 1803. "One of the most open and exposed of the buildings on Clifton Hill is Richmond Terrace, which forms three sides of a parallelogram, fronting respectively the east, south, and west; on the east side, not one family, and scarcely an individual, escaped the complaint; while on the south side, a great majority, both of persons and families, in all other respects similarly circumstanced, escaped it entirely." Such facts as these are among the few which afford solid grounds for medical reasoning; and they deserve the more attention, as they relate to circumstances of continual occurrence, and of perpetual influence on our health and comfort; and in proportion as both the medical and the meteorological sciences become founded on a firmer basis, it cannot be doubted that their beneficial effects will be more and more experienced, as well in the preservation of health as in the treatment and cure of diseases.

Clinical Medicine teaches us to investigate at the bedside of the sick, the true nature of the disease in the phenomena presented; to note their course and termination; and to study the effects of the various modes of treatment to which they are subjected. From this mode of study we learn the character of individual cases; theoretical study being competent to make us acquainted with species only. Clinical medicine demands therefore careful observation. It is in fact synonymous with experience. What advances would medicine have made, and from how many errors would it have been saved, if public instruction had always followed this natural course, so that pupils had received none but correct impressions and distinct conceptions of the phenomena of disease, and had attained a practical knowledge of the application of those rules and precepts, which dogmatical instruction always leaves indefinite!

We are unacquainted with the method of clinical instruction in medicine which was followed by the Asclepiades, but we cannot help admiring the results of it as exhibited to us in the writings of Hippocrates, who augmented the stores of experience inherited from them by following in their steps. After his time medicine ceased to be the property of particular families, and the path of experience by which it had been rendered so valuable was soon deserted. The slow progress of anatomy and physiology, the constant study of the philosophy of Aristotle, and endless disputes respecting the nature of man, of diseases and of remedies, occupied all the attention of physicians; and the wise method of observing and describing the diseases themselves fell into disuse.

Hospitals, at their origin, served rather as means of displaying the benevolence of the early Christians than of perfecting the study of medicine. The school of Alexandria was so celebrated, according to Ammianus Marcellinus, that a careful attendance upon its lessons entitled the student to pursue the practice of medicine. Another old and very thriving although less known institution, was situated at Nisapour, in Persia; and hospitals, even before the flourishing period of the Arabians, to whom the happy idea is commonly ascribed, were united with these medical institutions. The last school, founded by the emperor Aurelian, and superintended by Greek physicians, spread the doctrines of Hippocrates through all the East. It was supported for several centuries, and in it, without doubt, Rhazes, Al-Abbas, Avicenna, and the other celebrated Arabian physicians were instructed. At the same time, the celebrated John Mesue, of Damascus, was at the head of the hospital of Bagdad. Of the mode of instruction pursued there we know nothing; but we are inclined to form no very elevated opinion of the systems of an age which was devoted to all the dreams of Arabian *polypharmacy*. In truth, medicine shared the fate of all the other natural sciences in those barbarous ages. Men were little disposed to acquire slowly and cautiously the knowledge of disease at the bedside of the sick, in the manner of the Greek physicians.

It appears probable that the foundation of universities led to a renewed attention to the study of medical science; and we find accordingly, that in Spain, even under the dominion of the Arabians, there were schools and hospitals for the instruction of young physicians at Seville, Toledo, and Cordova. But even then, clinical studies were almost wholly neglected. Instead of studying the history of diseases, the pupils occupied their time with the most unprofitable pursuits. Not much more advantageous were the journeys that were made for the same objects to Italy and France, in the 11th and 12th centuries. The schools of Paris and Montpelier were those principally resorted to; but in these, the instruction consisted simply in lectures and endless commentaries upon the most obscure subjects; and even at the close of the 15th century, when the works of the Greek physicians began to be printed, men were still busied with verbal explanations and disputes. Two centuries elapsed before physicians returned to clinical studies and instructions. Among the renovators of this mode of studying medicine may be named, in Holland, William Von Straten, Otho Heurnius, and the celebrated Sylvius, about the middle of the 17th century; and it is said that clinical instruction was given at the same period in the schools of Hamburg, Vienna, and Strasburg. Even Boerhaave, who succeeded Sylvius as clinical instructor at Leyden, in 1714, has left us no journals of daily observation of disease, but only academic discourses upon the general principles of medicine.

The influence of this celebrated school was first perceived at Edinburgh, and afterwards at Vienna —two schools which, in celebrity for clinical instruction, soon eclipsed their common mother the school of Leyden. Cullen, one of the most celebrated teachers of practical medicine at Edinburgh, was too fond of fine-spun theories upon the condition of the diseased structures of the body, and the proximate causes of disease, ever to follow an uniform method in his lectures, and to adopt the entire history of disease, as observed at the bedside, as the basis of his system. From the account of what was effected in clinical medicine in Italy, Germany, and France, in the course of the 18th century, we may discover both the constantly increasing attention to this department of knowledge, and the difficulties with which such institutions are obliged to contend.

The Vienna school, by means of the labours of Van Swieten, De Haen, and still more of Stoll and of Franck, became a model of clinical study, since public lectures were given in the hospitals, and the simplicity of Grecian medicine successfully inculcated. The practice and study of medicine, in the hospitals in France, was only an indirect mode of gaining public confidence, till the period of the general revival of science, and the erection of the French *Ecole de Santé*. In that, for the first time, clinical instruction was expressly commanded.

At the present day, every good school has its establishment for clinical medicine connected with it; that is, an hospital in which diseases can be seen and studied by those attending it. In Germany, the empyrical or experimental mode of studying medicine was early given up for the more scientific form of lectures; while in England and France, the opposite extreme took place, and students were carried, as they sometimes are still, to the bedside of the sick, before they had been properly grounded in elementary studies. In Germany there are very numerous journals which contain clinical reports of cases, as there are so many clinical institutions appropriated to particular classes of disease.

We may cite the London Hospital, which has flourished under the fostering care of Sir W. Blizard for more than half a century, as one of the most perfect in the metropolis.

The clinical school is called *ambulatory*, when the patients attend only at particular hours; and it is termed *polyclinic*, when the instructer and his pupils visit together the beds of the sick.

Clock. For many inventions which do honour to the human mind, we are indebted to the monks of the middle ages, who in their seclusion, free from the necessity of providing for their support, employed the time during which they were not engaged in their devotions in the practice of various useful arts. Among the inventions which we owe to them are clocks or time-keepers, which are set in motion by wheels, pendulums, and steel springs. The word *horologium* was in use even among the ancients; and it might almost be inferred, from many expressions, that they possessed instruments similar to our pocket-watches and chamber-clocks. It is however certain, that their time-pieces were sun-dials, hour-glasses, and clepsydræ. The latter, Julius Cæsar brought with him from Great Britain. It was a clepsydra which Cassiodorus, in the 6th century, recommended to his monks, when a cloudy sky prevented them from observing their sun-dials.

The gourmand Trimalchio, described by Petronius, had a clepsydra in his dining-room, and placed a trumpeter near it to announce the hours. Vitruvius mentions an Alexandrian artist who, 140 years before our era, combined spring-wheels with the clepsydra; but the account is too confused and incomplete to afford a correct idea of its construction. In an old chronicle it is related, that Charlemagne received a clock from Haroun al Raschid in 809, to which small

CLOCK WORK.

bells were attached, and in which figures of horsemen, at the hour of twelve, came forth through little doors, and retired again. There is a more exact description of this work of art in the Franconian annals, attributed to Eginhard, in which it is particularly said to have been a clepsydra, and that, at the end of each hour, little balls of metal fell upon a bell, and produced a sound. It is not probable that the clock which Pacificus, archdeacon of Verona, is said to have invented in the 9th century, could have been equal to our present clocks. The words on his tomb are so indistinct that nothing positive can be inferred from them.

The discovery of clocks has likewise been attributed to the famous Gerbert of Auvergne, who afterwards became pope under the name of *Sylvester II.*, and died in 1003; but Ditmar of Merseburg, a trustworthy witness, only relates that Gerbert placed a *horologium* in Magdeburg for the emperor Otho, after observing through a tube, the star which guides the seamen. This must have been a sun-dial, which Gerbert placed according to the height of the pole.

In the 12th century clocks were made use of in the monasteries, which announced the end of every hour by the sound of a bell, put in motion by means of wheels. From this time forward, the expression "the clock has struck" is often met with. The hand for marking the time is also made mention of. Of William, abbot of Hirschau, his biographer relates, that he invented a *horologium* similar to the celestial hemisphere. Short as this account is, it still appears probable that this abbot was the inventor of clocks, as he employed a person particularly in arranging his work, and keeping it in order. This abbot died at the end of the 11th century.

In the 13th century there is again mention of a clock, given by Sultan Saladin, to the emperor Frederick II. This was evidently put in motion by weights and wheels. It not only marked the hours, but also the course of the sun, of the moon, and the planets in the zodiac. It is hardly probable that the Saracens learned the art of clock-making from the monks of European monasteries: perhaps, on the contrary, they were the real inventors of it, and the invention was made known to the Europeans by means of the crusades. In the 14th century, there are stronger traces of the present system of clock-work. Dante particularly mentions clocks.

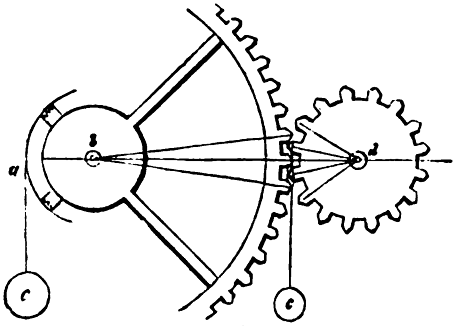
The manufacture of clocks appears to have been introduced into England during the reign of Edward III., as that monarch, in the year 1368, invited three Dutch *Arlogiers* from Delft, for the express purpose of benefiting his subjects by a knowledge of the art. But the oldest clock extant in this country towards the close of the last century, was made in the reign of Henry VIII. It was honoured by a place in the royal palace at Hampton, and was so constructed as to represent the motions of the heavenly bodies. It is a curious fact, that in the writings of two of our best poets, we find the surest data that can be adduced of the early use of clocks and watches in this country. Chaucer, who was born in 1328, says:—

> "Full sickerer was his crowing in his loge,
> As is a *clock*, or any abbey *orloge*."

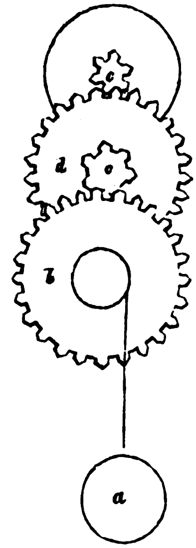
Shakspeare is equally conclusive as to the general use of watches in the time of Elizabeth:—

> "I frown the while, and perchance *wind up my watch*, or play with some rich jewel."—MALVOLIO in "*Twelfth Night*."

As the construction of every modern horological machine must depend mainly on a judicious combination of wheel-work, it may be advisable to examine first the principle of a common wheel and pinion, and then show its application to the movement of a clock.



In the above diagram, the pinion *d* is supported by a separate axis, round which it is made to revolve; and the wheel, *i*, being three times as large as the pinion, the latter will make three revolutions to one of the former, or about one revolution for the portion of a circle shown in the diagram. If we consider the weight *c* as the maintaining power, it will be evident, that for every revolution made by its axis there will be three revolutions of the next wheel in succession.



If we combine a series of wheels and pinions, a still greater increase in speed will result. Thus it will be seen, that there are four revolutions of the pinion *c* for one of the wheel that drives it; and as the wheel *d* is attached to the same axis, the pinion *e* will make sixteen revolutions to one of the prime mover.

A reference to this simple mode of increasing velocity in wheel-work will readily explain why a clock which makes but twelve revolutions at the barrel, is enabled to beat half and quarter seconds, and even go as many days as there are turns at the prime mover.

We pass now to a complete clock, intended to go by the impulse of a weight, and for greater clearness take one constructed on the original balance principle. It is represented in our *plate* CLOCK-WORK, *fig.* 1. The maintaining power or weight, *a*, is seen suspended beneath. It acts on the barrel, *b*, to which is attached a large wheel. The teeth of the barrel-wheel gives motion to the pinion, *c*, which carries the minute hand, *d*. A small nut, at *e*, gives motion to the hour-wheel, *f*. Having thus obtained the division of minutes and hours, the next step is to regulate the motion of the "train" of wheels and pinions: this is effected by the escapement, which consists in the present case of a wheel, *g*, and balance, *h*. The pallets, *i*, *i*, are

intended alternately to take the teeth of the wheel in which they act. This produces the ticking sound, so audible in every species of clock. The balance, *h*, with its weights, continually oscillates backwards and forwards, and by its slow regular motion gives uniformity to the operation of the wheel-work of the clock.

A portable clock is represented at *fig.* 2. Here a bent spring is substituted for the weight. The spring is coiled in the barrel, *k*, and the chain being wound round the fusee, gives motion to the train, as in the former case. The fusee is tapered from the bottom upwards: this is intended to equalize the power of the spring, which when wound quite up, pulls with greater force when its coils are less tightened. In *fig.* 3, the anchor escapement is represented with the wheel detached from the train. Here again the same species of oscillation in the pendulum is employed to regulate the wheel-work. *Fig.* 4, exhibits the dead-beat of Graham, in which the seconds' hand is left in a state of rest between each oscillation of the pendulum. See ESCAPEMENT.

If any substance, sufficiently long for a pendulum, could be found in nature, that has not its dimensions enlarged or diminished by heat or cold, such substance would be the most suitable for a simple attached pendulum; but all attempts to discover such a substance have hitherto been ineffectual. Hence, contrivances have been devised by ingenious men, to counteract the effects of variable temperature in the pendulum, and some of them have succeeded in effecting this desirable purpose. So long ago as the year 1648, the different expansibilities of various metals were known by Wandelim to exist, and in 1715, that ingenious artist, George Graham, made several experiments with the pyrometer, invented by Musschenbrock, to ascertain the relative quantities of expansion in different metals, with a view of availing himself of the difference of the expansions of some two or more metals, when opposed to each other, in the construction of a compensating pendulum; but the difference which he detected, between iron and brass, for instance, was so small, that he relinquished all hope of being able to accomplish his object in this way, and therefore gave up the project. (*Phil. Trans.* London, 1726.) However, it occurred to the same artist, that mercury was affected by changes of heat and cold, sufficiently to answer the purpose of keeping the centre of oscillation of a pendulum always equidistant from the point of suspension, provided the mercury could be made to ascend while the verge of the pendulum descended, or elongated, by any degree of heat; and *vice versâ*. In 1721, the trial was made in a pendulum, which we shall presently describe, and in which the compensation, after some adjustment, was found so complete, that its error in the extremes of temperature was reduced to $\frac{1}{8}$ of the quantity observable in an ordinary simple pendulum. In the mean time, the idea of arranging metallic bars of different expansibilities in such a manner as to constitute a good compensating pendulum, being once suggested by Graham's paper on the subject, roused the ingenuity of different mechanics; and Harrison, a carpenter, of Barton, in Lincolnshire, in the year 1726, succeeded in completing the requisite arrangement. His rods of metal were placed in such parallel situations as to resemble those of a gridiron, from which circumstance the pendulum, so constructed, has been denominated the *gridiron pendulum*. Since Harrison's time, there have been various modifications of the compensating pendulum, both in England and France, the principal of which we shall describe in their order of time, but none of them have been found to excel the prototypes of Graham and Harrison, which are still used, one or other of them, in the principal observatories. If any improvement has been made on the original pendulums, it is in the external appearance, and in the easier modes of adjustment. (See PENDULUM.)

CLOSE-HAULED, in navigation; the general arrangement or trim of a ship's sails, when she endeavours to make progress, in the nearest direction possible, towards that point of the compass from which the wind blows.

CLOSE-QUARTERS; certain strong barriers of wood, stretching across a merchant-ship in several places. They are used as a place of retreat when a ship is boarded by her adversary, and are therefore fitted with several small loopholes, through which to fire the small arms. They are likewise furnished with several small caissons, called *powder-chests*, which are fixed upon the deck, and filled with powder, old nails, &c., and may be fired at any time. Instances are known in which close-quarters have proved highly effective.

CLOTH. See WEAVING and WOOLLEN.

CLOTHING. A very striking fact, exhibited by the bills of mortality, is the very large proportion of persons who die of consumption. It is not our intention to enter into any general remarks upon the nature of that fatal disease. In very many cases, the origin of a consumption is an ordinary cold; and that cold is frequently taken through the want of a proper attention to clothing, particularly in females. We shall, therefore, offer a few general remarks upon this subject, so important to the health of all classes of persons. Nothing is more necessary to a comfortable state of existence, than that the body should be kept in nearly an uniform temperature. The Almighty Wisdom, which made the senses serve as instruments of pleasure for our gratification, and of pain for our protection, has rendered the feelings arising from excess or deficiency of heat so acute, that we instinctively seek shelter from the scorching heat and freezing cold. We bathe our limbs in the cool stream, or clothe our bodies with the warm fleece. We court the breeze, or carefully avoid it. But no efforts to mitigate the injurious effects of heat or cold would avail us, if nature had not furnished us, in common with other animals (in the peculiar functions of the skin and lungs), with a power of preserving the heat of the body uniform under almost every variety of temperature to which the atmosphere is liable. The skin, by increase of the perspiration, carries off the excess of heat; the lungs, by decomposing the atmosphere, supply the loss; so that the internal parts of the body are preserved at a temperature of about 98°, under all circumstances. In addition to the important share which the function of perspiration has in regulating the heat of the body, it serves the farther purpose of an outlet to the constitution, by which it gets rid of matters that are no longer useful in its economy. The excretory function of the skin is of such paramount importance to health, that we ought at all times to direct our attention to the means of securing its being duly performed; for if the matters that ought to be thrown out of the body by the pores of the skin are retained,

they invariably prove injurious. When speaking of the excrementitious matter of the skin, we do not mean the sensible moisture which is poured out in hot weather, or when the body is heated by exercise, but a matter which is too subtile for the senses to take cognizance of, which is continually passing off from every part of the body, and which has been called the *insensible perspiration*. This insensible perspiration is the true excretion of the skin. A suppression of the insensible perspiration is a prevailing symptom in almost all diseases. It is the sole cause of many fevers. Very many chronic diseases have no other cause. In warm weather, and particularly in hot climates, the functions of the skin being prodigiously increased, all the consequences of interrupting them are proportionably dangerous. Besides the function of perspiration, the skin has, in common with every other surface of the body, a process, by means of appropriate vessels, of absorbing, or taking up, and conveying into the blood-vessels, any thing that may be in contact with it. It is also the part on which the organ of feeling or touch is distributed. The skin is supplied with glands, which provide an oily matter, that renders it impervious to water, and thus secures the evaporation of the sensible perspiration. Were this oily matter deficient, the skin would become sodden, as is the case when it has been removed—a fact to be observed in the hands of washerwomen, when it is destroyed by the solvent powers of the soap. The hair serves as so many capillary tubes to conduct the perspired fluid from the skin. The three powers of the skin, perspiration, absorption, and feeling, are so dependent on each other, that it is impossible for one to be deranged without the other two being also disordered. For if a man be exposed to a frosty atmosphere, in a state of inactivity, or without sufficient clothing, till his limbs become stiff and his skin insensible, the vessels that excite the perspiration and the absorbent vessels partake of the torpor that has seized on the nerves of feeling; nor will they regain their lost activity till the sensibility be completely restored. The danger of suddenly attempting to restore sensibility to frozen parts is well known. If the addition of warmth be not very gradual, the vitality of the part will be destroyed. This consideration of the functions of the skin will at once point out the necessity of an especial attention, in a fickle climate, to the subject of clothing. Every one's experience must have shown him how extremely capricious the weather is in this country. Our experience of this great inconstancy in the temperature of the air ought to have instructed us how to secure ourselves from its effects. The chief end proposed by clothing ought to be protection from the cold; and it never can be too deeply impressed on the mind (especially of those who have the care of children), that a degree of cold that amounts to shivering cannot be felt, under any circumstances, without injury to the health, and that the strongest constitution cannot resist the benumbing influence of a sensation of cold constantly present, even though it be so moderate as not to occasion immediate complaint, or to induce the sufferer to seek protection from it. This degree of cold often lays the foundation of the whole host of chronic diseases, foremost amongst which are found scrofula and consumption. Persons engaged in sedentary employments must be almost constantly under the influence of this degree of cold, unless the apartment in which they work is heated to a degree that subjects them, on leaving it, to all the dangers of a sudden transition, as it were, from summer to winter. The inactivity to which such persons are condemned, by weakening the body, renders it incapable of maintaining the degree of warmth necessary to comfort, without additional clothing or fire. Under such circumstances, a sufficient quantity of clothing, of a proper quality, with the apartment moderately warmed and well ventilated, ought to be preferred, for keeping up the requisite degree of warmth, to any means of heating the air of the room so much as to render any increase of clothing unnecessary. To heat the air of an apartment much above the ordinary temperature of the atmosphere, we must shut out the external air; the air also becomes extremely rarefied and dry; which circumstances make it doubly dangerous to pass from it to the cold, raw, external air. But in leaving a moderately well-warmed room, if properly clothed, the change is not felt; and the full advantage of exercise is derived from any opportunity of taking it that may occur.

The only kind of dress that can afford the protection required by the changes of temperature to which high northern climates are liable, is *woollen*. Nor will it be of much avail that woollen be worn, unless *so much* of it be worn, and it be *so* worn, as effectually to keep out the cold. Those who would receive the advantage which the wearing of woollen is capable of affording, must wear it next the skin; for it is in this situation only that its health-preserving power can be felt. The great advantages of woollen cloth are briefly these:—the readiness with which it allows the escape of the matter of perspiration through its texture; its power of preserving the sensation of warmth to the skin under all circumstances; the difficulty there is in making it thoroughly wet; the slowness with which it conducts heat; the softness, lightness, and pliancy of its texture. *Cotton cloth*, though it differs but little from linen, approaches nearer to the nature of woollen, and, on that account, must be esteemed as the next best substance of which clothing may be made. *Silk* is the next in point of excellence, but it is inferior to cotton in every respect. *Linen* possesses the contrary of most of the properties enumerated as excellences in woollen. It retains the matter of perspiration in its texture, and speedily becomes imbued with it; it gives an unpleasant sensation of cold to the skin; it is very readily saturated with moisture, and it conducts heat too rapidly. It is, indeed, the worst of all the substances in use, being the least qualified to answer the purposes of clothing. There are several prevailing errors in the mode of adapting clothes to the figure of the body, particularly amongst females. Clothes should be so made as to allow the body the full exercise of all its motions. The neglect of this precaution is productive of more mischief than is generally believed. The misery and suffering arising from it begin while we are yet in the cradle. When they have escaped from the nurses' hands, boys are left to nature. Girls have, for a while, the same chance as boys, in a freedom from bandages of all kinds; but, as they approach to womanhood, they are again put into trammels in the forms of stays. The bad consequences of the pressure of stays are not immediately obvious, but they are not the less certain on that account. The girl writhes and twists to avoid the pinching which must necessarily attend the commence-

ment of wearing stays tightly laced. The posture in which she finds ease is the one in which she will constantly be, until at last she will not be comfortable in any other, even when she is freed from the pressure that originally obliged her to adopt it. In this way most of the deformities to which young people are subject originate; and, unfortunately, it is not often that they are perceived until they have become considerable, and have existed too long to admit of remedy.

CLOUD. The clouds are aqueous vapours, suspended in the atmosphere. They differ from fogs only by their height and less degree of transparency. The cause of the latter circumstance is the thinness of the atmosphere in its higher regions, where the particles of vapour become condensed. The varieties of clouds are numerous. Some cast a shade which covers the sky, and at times produces a considerable darkness; others resemble a light veil, and permit the rays of the sun and moon to pass through them. Clouds originate like fogs.

The watery evaporations which rise from seas, lakes, ponds, rivers, and, in fact, from the whole surface of the earth, ascend, on account of their elasticity and lightness, in the atmosphere, until the air becomes so cold and thin that they can rise no higher, but are condensed. Philosophers, however, are of very different opinions respecting the way in which the condensation, and the whole formation of the clouds, proceed. De Luc, whose theory is considered the most probable, believes that the water, after its ascent in the form of vapours, and before it takes the shape of clouds, exists in a gaseous state, not affecting the hygrometer, which is the reason why the air in the higher regions is always dry. He explains the clouds to be collections of small vesicles, in the transformation of which from the gaseous state, he believes that caloric operates, in part at least, because, according to his opinion, clouds communicate a degree of heat to the body which they render damp.

According to Huber, clouds are collections of precipitated spherules, and differ by their negative electricity from fogs, the electricity of which is generally positive. If clouds and fogs lose their electricity, rain is produced. These explanations are, however, by no means perfectly satisfactory.

The change of winds contributes essentially to the formation of clouds and fogs. In countries where this change is small and infrequent, as between the tropics, these phenomena of humidity in the atmosphere must be comparatively rare, but, when they happen, the more violent, because a great quantity of vapour has had time to collect. The distance of the clouds from the surface of the earth is very different. Thin and light clouds are higher than the highest mountains; thick and heavy clouds, on the contrary, touch low mountains, steeples, and even trees.

The average height of the clouds is calculated to be two miles and a half. Their size is likewise very different. Some have been found occupying an extent of 20 square miles, and their thickness, in some cases, has been ascertained by travellers who have ascended mountains, to be a thousand feet: others are very thin, and of small dimensions. The natural history of clouds, not as respects their chemical structure, but their forms, their application to meteorology, and a knowledge of the weather, has been well treated by Luke Howard, in his *Essay on Clouds*. He distributes clouds into three essentially different formations. These formations are—1. *cirrus*, consisting of fibres which diverge in all directions; 2. *cumulus*, convex and conical aggregates, which increase from a horizontal basis upwards; 3. *stratus*, layers vastly extended, connected, and horizontal. The clouds are generally assigned to three atmospherical regions, the upper, the middle, and the lower one, to which a fourth, the lowest, may be added. In the upper region, the atmosphere is in such a state, that it can receive and sustain aqueous matter dissolved into its integrant parts. This state of the atmosphere corresponds to the highest state of the barometer. To this region belongs the *cirrus*, which has the least density, but the greatest height, and variety of shape and direction.

It is the first indication of serene and settled weather, and first shows itself in a few fibres, spreading through the atmosphere. These fibres by degrees increase in length, and new fibres attach themselves to the sides. The duration of the *cirrus* is uncertain, from a few minutes to several hours. It lasts longer, if it appears alone, and at a great height; a shorter time, if it forms in the neighbourhood of other clouds. The middle region is the seat of *cumulus*, which is generally the most condensed, and moves with the stream of air nearest to the earth. This region can receive much humidity, but not in perfect solution. The humidity becomes collected, and shows itself in masses rising conically, and resting on the third region. The appearance, increase, and diappearance of the *cumulus*, in fine weather, are often periodical, and correspondent to the degree of heat. Generally, it forms a few hours after sun-rise, attains its highest degree in the hottest hours of the afternoon, and decreases and vanishes at sun-set. Great masses of *cumulus*, during high winds, in the quarter of the heavens towards which the wind blows, indicate approaching calm and rain. If the *cumulus* does not disappear, but rises, a thunderstorm is to be expected during the night. If the upper region with its drying power predominates, the upper parts of the *cumulus* become *cirrus*. But if the lower region predominates (into which the densest vapours are attracted and dissolved into drops), the basis of the *cumulus* sinks, and the cloud becomes *stratus*, which is of moderate density, and its lower surface rests generally upon the earth or the water. This is the proper evening cloud, and appears first towards sun-set. To this belong also those creeping fogs, which in calm evenings ascend from the valleys, and extend themselves in undulating masses. The *stratus* remains quiet, and accumulates layers, till at last it falls as rain. This phenomenon —the dissolution of clouds into rain—is called *nimbus*.

Howard farther makes subdivisions, as, *cirro-cumulus*, *cirro-stratus*, &c. Also the real *stratus*, the horizontal layer of clouds, sometimes rises higher than at other times, which depends on the season, the polar height of the place, or the heights of mountains: the *cumulus* is also sometimes higher and sometimes lower. On the whole, however, the different kinds remain one above another. Thomas Forster has followed Howard in his investigations respecting the clouds, and Goëthe, the German poet, has made an application of this theory in his work entitled *Zur Naturwissenschaft*.

CLOVE. The clove is the unexpanded flower-bud of an East Indian tree somewhat resembling the laurel in its height, and in the shape of its leaves. It appears that, in 1770 and 1772, both clove and nutmeg-trees were transplanted from the Moluccas into the islands of France and Bourbon, and subsequently into some of the colonies of South America, where they have since been cultivated with great success. At a certain season of the year, the clove-tree produces a vast profusion of flowers. When these have attained the length of about half an inch, the four points of the calyx being prominent, and having in the middle of them the leaves of the petals folded over each other, and forming a small head about the size of a pea, they are in a fit state to be gathered. This operation is performed betwixt the months of October and February, partly by the hand, partly by hooks, and partly by beating the trees with bamboos. The cloves are either received on cloths spread beneath the trees, or are suffered to fall on the ground, the herbage having been previously cut and swept for that purpose. They are subsequently dried by exposure for a while to the smoke of wood fires, afterwards to the rays of the sun. When first gathered, they are of a reddish colour, but by drying, they assume a deep brown cast. This spice yields a very fragrant odour, and has a bitterish, pungent, and warm taste. It is sometimes employed as a hot and stimulating medicine, but is more frequently used in culinary preparations. When fresh gathered, cloves will yield, on pressure, a fragrant, thick, and reddish oil; and by distillation, a limpid essential oil. Oil of cloves is used by many persons, though very improperly, for curing the tooth-ache; since, from its pungent quality, it is apt to corrode the gums and injure the adjacent teeth. When the tooth is carious, and will admit of it, a bruised clove is much to be preferred.

The duty on cloves was considerably reduced in 1819; and there has, in consequence, been a decided increase in the consumption of the article; though not nearly so great as it would have been, had it been supplied under a more liberal system. The cloves at present entered for home consumption in Great Britain, amount to about 60,000 lbs. per year, of which a part comes from Cayenne. But the cultivation of the clove in Cayenne depends entirely on the existence of the present system in the Moluccas. The superiority which the latter enjoy over every other place in the production of cloves, is so very great, that were any thing like freedom given to those engaged in their culture, they would very speedily exclude every other from the market.

CLOVE BARK, or CULILAWAN BARK, is furnished by a tree of the Molucca Islands. It is in pieces more or less long, almost flat, thick, fibrous, covered with a white epidermis, of a reddish-yellow inside, of a nutmeg and clove odour, and of an aromatic and sharp taste. It is one of the substitutes for cinnamon, but not much used. We find also in commerce, under the name of *clove-bark*, another bark furnished by the *myrthus caryophillata*. It is in sticks two feet long, formed of several pieces of very thin and hard bark, rolled up one over the other, of a deep brown colour, of a taste similar to that of cloves. It possesses the same properties as the former barks, and may be considered as a substitute for them.

CLUE, of a sail, is the lower corner; and hence *clue-garnets* are a sort of tackles fastened to the clues of the mainsail and foresail, to truss them up to the yard, which is usually termed *clueing-up* the sails. *Clue-lines* are used for the same purpose as clue-garnets, only that the latter are confined to the courses, whilst the clue-lines are common to all the square-sails.

COACH. See CARRIAGE.

COALITION, in chemistry; the reunion or combination of parts which had before been separated.

COALS. See MINE.

COAT OF ARMS; 1. the surcoat worn by a knight; 2. the ensigns armorial of a family; so called, because originally worn on some part of the armour. Their origin is to be referred to the age of chivalry, when they were assumed as emblematic of the adventures, love, hopes, &c., of the knight, and were useful for distinguishing individuals, whom it was difficult to recognize, covered as they were from head to foot with armour. This, perhaps, may even have been the origin of the usage. As every thing else became hereditary in Europe,—estates, dignities, titles, privileges,—so the favourite emblem of the knight became the adopted badge of the family, the figures or characters employed in them began to receive names, and the language and science of heraldry (see HERALDRY) was formed. The right to bear arms thus became a distinctive mark of gentle birth.

COBALT occurs alloyed with arsenic, nickel, and other metals, and mineralized by oxygen and by arsenic acid. It is obtained, after the ore has been roasted and calcined, in the state of an oxide, impure from the presence of other metallic oxides. When this oxide is obtained in a state of purity, and reduced to the metallic state, we are presented with a metal of a white colour, inclining to gray, and if tarnished, to red, with a moderate lustre. Its fracture is compact; it is hard, brittle, and of a specific gravity of 7.8. Like nickel, it is sensibly magnetic, and is susceptible of being rendered permanently so. It undergoes little change in the air, but absorbs oxygen when heated in open vessels. It is attacked with difficulty by sulphuric or muriatic acid, but is readily oxidized by means of nitric acid. There are but two oxides of cobalt known. The protoxide is of an ash gray colour, and is the basis of the salts of cobalt, most of which are of a pink hue. When heated to redness in open vessels, it absorbs oxygen, and is converted into the peroxide. It may be prepared by decomposing the carbonate of cobalt by heat, in a vessel from which the atmospheric air is excluded. It is easily known by its giving a blue tint to borax when melted with it, and is employed in the arts, in the form of smalt, for communicating a similar colour to glass, to earthenware, and to porcelain.

Smalt, or powder blue, is made by melting three parts of fine white sand, or calcined flints, with two of purified pearl-ash and one of cobalt ore, previously calcined, and lading it out of the pots into a vessel of cold water; after which, the dark-blue glass, or zaffre, is ground, washed over, and distributed into different shades of colours, which shades are occasioned by the different qualities of the ore, and the coarser and finer grinding of the powder. Smalt, besides being used to stain glass and pottery, is often substituted in painting, for ultra-marine blue, and is likewise employed to give to paper and linen a bluish tinge.

The muriate of cobalt is celebrated as a *sympathetic ink*. When diluted with water, so as to form a pale

pink solution, and then employed as ink, the letters which are invisible in the cold, become blue if gently heated. It is prepared by dissolving one part of zaffre in two of diluted nitric acid, with the aid of heat, adding to it of muriate of soda one part, and diluting with twenty parts of water. The peroxide of cobalt is of a black colour, and is easily formed in the way already mentioned. It does not unite with acids; and, when digested in muriatic acid, the proto-muriate of cobalt is generated with the disengagement of chlorine. When strongly heated in close vessels, it gives off oxygen, and is converted into the protoxide.

Ores of cobalt: 1. *White cobalt ore*, or *bright white cobalt ore*, consists principally of cobalt and arsenic. Its colour is tin-white, liable to tarnish, with little lustre. It occurs massive and crystallized, in cubes and in octohedrons. It is hard and brittle. Specific gravity, 7.3 to 7.7. Before the blow-pipe it melts, and gives an arsenical smoke and odour. It forms a metallic globule, and gives to borax a blue colour. It occurs chiefly in primitive rocks, and is frequently accompanied with bismuth. It is found most abundantly in Germany, Sweden, and Norway, and also occurs in several other European countries. 2. *Gray cobalt ore* is an alloy of cobalt with arsenic and iron, and is sometimes accompanied with small portions of nickel and bismuth. Its colour is light-gray; liable to tarnish. It occurs massive or disseminated, and is never crystallized. It has been found in the United States, at Chatham, Connecticut, but has not hitherto been worked advantageously. It also occurs in Bohemia, Saxony, and France. 3. *Red cobalt ore* is a hydrated arseniate of cobalt, of a beautiful peach blossom red colour. It occurs massive, disseminated, and in minute crystals. It accompanies other ores of cobalt.

Cockswain, or Coxen; the officer who manages and steers a boat, and has the command of a boat's crew. It is evidently compounded of the words *cock* and *swain*, the former of which was anciently a yawl, or small boat, as appears from several authors, but has now become obsolete.

Codex; with the ancients, that part of the wood of a tree next to the bark. Before the invention of paper, wooden tablets, covered with wax, which were written on with the style, and put together in the shape of a book, were called *codex*. The word was afterwards retained, in times when paper was used for writing, to denote a large book. Thus, important works, particularly old manuscripts of poets, historians, &c., which had been preserved, were called *codices manuscripti*. See Manuscripts.

Coefficients, in algebra; figures put before the letters, to indicate how many times the letter is to be added to itself. Thus $4a$ signifies $a+a+a+a$. If the coefficient is indefinite, it is expressed by a letter, as $b\,a$.

Coffee. The natural history of this valuable plant will be found under that division of our work, but its commercial importance must be noticed here. Coffee is an article of but recent introduction. To the Greeks and Romans it was wholly unknown. Its use appears to have originated in Ethiopia; and it is stated to have been first introduced into Constantinople in 1554, from whence it was gradually adopted in the western parts of Europe. The information we have respecting its introduction into England is, that, in 1652, Daniel Edwards, a Turkey merchant, brought home with him a Greek servant, whose name was *Pasqua*, and who understood the methods of roasting coffee, and making it into a beverage. This man was the first who publicly sold coffee in England, and kept a house for that purpose in George Yard, Lombard Street. At Paris, coffee was nearly unknown, until the arrival of the Turkish ambassador, Solomon Aga, in 1669; about three years after which the first coffee-house is said to have been established in that city. The coffee shrub was originally planted in Jamaica in 1732.

Great attention is paid to the culture of coffee in Arabia. The trees are raised from seed sown in nurseries, and afterwards planted out in moist and shady situations, on sloping grounds, or at the foot of mountains. Care is taken to conduct little rills of water to the roots of the trees, which at certain seasons require to be constantly surrounded with moisture. As soon as the fruit is nearly ripe, the water is turned off, lest the fruit should be rendered too succulent. In places much exposed to the south, the trees are planted in rows, and are shaded from the otherwise too intense heat of the sun, by a branching kind of poplar-tree. When the fruit has attained its maturity, cloths are placed under the trees, and upon these the labourers shake it down. They afterwards spread the berries on mats, and expose them to the sun to dry. The husk is then broken off by large and heavy rollers of wood or iron. When the coffee has been thus cleared of its husk, it is again dried in the sun, and, lastly, winnowed with a large fan, for the purpose of clearing it from the pieces of husks with which it is intermingled. A pound of coffee is generally more than the produce of one tree; but a tree in great vigour will produce three or four pounds.

The best coffee is imported from Mocha, on the Red Sea. This kind, which is denominated *Mocha* and *Turkey coffee*, is of a better quality than any which the European colonists are able to raise, owing, as it is supposed, to the difference of climate and soil in which it grows. It is packed in large bales, each containing a number of smaller bales, and when good, appears fresh, and of a greenish-olive colour. The coffee next in esteem to this is raised in Java and the East Indies; and that of lowest price, in the West Indies and Brazil. When stowed in ships, with rum, pepper, or other articles, it is said that coffee contracts a rank and unpleasant flavour; and this has been assigned as a reason of the inferiority of that which is imported from the European plantations.—The quantity of coffee annually supplied by Arabia is supposed to be upwards of 14,000,000 of pounds. Before the commencement of the French revolution, the island of St. Domingo alone exported more than 70,000,000 of pounds per annum; and, at the present day, such is the fertility of this island, that sufficient coffee is raised to reduce the price greatly in all parts of the civilized world. Almost all the Mohammedans drink coffee at least twice a day, very hot, and without sugar.

The excellence of coffee depends in a great measure on the skill and attention exercised in roasting it. If it be too little roasted, it is devoid of flavour, and if too much, it becomes acrid, and has a disagreeable burnt taste. In Europe, it is usually roasted in a cylindrical tin box, perforated with numerous holes, and fixed upon a spit, which runs lengthwise through the centre, and is turned by a jack, or by the hand. Coffee is used in the form either of an infu-

sion or decoction, of which the former is decidedly preferable, both as regards flavour and strength. Coffee, as very commonly prepared by persons unacquainted with its nature, is a decoction, and is boiled for some time, under a mistaken notion that the strength is not extracted unless it be boiled. But the fact is just the reverse. The fine aromatic oil, which produces the flavour and strength of coffee, is dispelled and lost by boiling, and a mucilage is extracted at the same time, which also tends to make it flat and weak. The best modes are, to pour boiling water through the coffee in a biggin or strainer, which is found to extract nearly all the strength; or to pour boiling water upon it, and set it upon the fire, not to exceed ten minutes. Prepared in either way, it is fine and strong. As a medicine, strong coffee is a powerful stimulant and cordial, and in paroxysms of the asthma is one of the best remedies; but it should be very strong, and made with almost as much coffee as water. In faintness or exhaustion from labour and fatigue, and from sickness, coffee is one of the most cordial and delicious restoratives. There are coffee-machines, in which the water is boiled, and the steam penetrates the coffee, and extracts, to a great degree, the fine aroma. Immediately after, the boiling water is poured over it. Thus the best coffee is made. As we have already said, in Europe, coffee is generally roasted in a cylinder; in Asia, however, open pans or tin plates are used, and, if the time allows, a boy is employed, who picks out every bean when it has reached the right degree of brownness. The same is done by some French people. The second difference in the Asiatic way of preparing coffee is, that they pound the beans, and do not grind them, much preferring the former mode. In Marseilles, we have seen coffee likewise pounded. Whether this is really preferable, we do not venture to decide; but experience has taught us that the Asiatic coffee is, on the whole, much better than the European. The difference is probably owing to the different way of roasting. The Turks and Arabs boil the coffee, it is true, but they boil each cup by itself, and only for a moment, so that the effect is, in fact, much the same as that of infusion, and not like that of decoction. They do not separate the coffee itself from the infusion, but leave the whole in the cup. It improves the beverage very much to roast and grind the coffee just before it is used.

The Turks drink coffee at all times of day, present it to visitors both in the forenoon and afternoon, and the opium-eater lives almost entirely on coffee and opium. Beaujour, in his excellent work on Greece, tells of a *theriacophage* (an opium-eater), who drank more than 60 cups of coffee in a day, and smoked as many pipes. Coffee has been the favourite beverage of many distinguished men. Napoleon and Frederick the Great drank it freely; Voltaire liked it very strong; and Leibnitz drank it also during the whole day, but mixed with more than an equal quantity of milk. The best coffee, in the western part of the world, is made in France, where this beverage is in universal request. In fact, throughout the continent of Europe it is generally drank. In England, however, tea is a more common drink. In England and the United States, coffee, almost always, is badly made. The coffee-houses in France, it is well known, are places which afford much opportunity for interesting observation. In the south of France, they are still more frequented than in the north. The different *Cafés* of the *Palais Royal* in Paris are famous: the *Café des Mille Colonnes* is one of the most splendid. The *Café de la Paix* contains a small theatre. In the *Café des Aveugles*, every evening, blind men and women of the *Hospice des Quinze-Vingts* play and sing. Those coffee-houses in France where smoking is allowed, are called *estimanets*, which is also the name of the beer-houses in Holland. One of the greatest attractions in French coffee-houses is the *limonadière*, a woman who sits in an elevated seat, to attend to the sale of the refreshments. She is generally very pretty, and is dressed with much taste. With genuine French tact, she represses all improper freedoms.

In the East, the coffee-houses, or rather booths, form a very essential part of the social system; all men of leisure assembling there. In these places are also to be found the famous story-tellers, who repeat long tales to attentive hearers, who show their interest by exclamations of "God save him! Allah deprive him of his eyes!" &c., or utter warning cries to alarm the hero when danger awaits him. It often happens that the story is broken off and continued the next day. There is a highly interesting manuscript in the Royal Library at Paris, in Arabic, entitled the *Support of Innocence*. It relates to the lawfulness of using coffee. The author is Aljeziri Alhanbali. Of this De Sacy gives an account and extracts in his *Chrestomathie Arabe*. It appears that a question arose, whether coffee was to be included among the intoxicating beverages which the Koran prohibits; and the manuscript proves that it is not. There are many other interesting matters in these extracts. The sheikh, the writer of the manuscript, proves that the use of coffee was first introduced by a famous sheikh, imaum, mufti and scholar of Arabia Felix, called *Dhabani*, about the year 870 of the Hegira.

In Egypt, the drinking of coffee seems to have been at first regarded almost as a religious ceremony. The devotees, who introduced it there, assembled for the purpose of enjoying it on Monday and Friday evenings, when it was handed round with great solemnity, accompanied with many prayers, and ever and anon with exclamations of "There is no God but God!" There are also mentioned, in the manuscript above cited, two different methods of making coffee, one called *buniyya*, in which the grain and husk are used together, and another called *kishariyya*, in which the husk is used alone. Many sermons against coffee-drinking are extant, written at the time when it was introduced into Europe; as there are also many sermons against smoking. We recollect having read the following passage in an old sermon: "They cannot wait until the smoke of the infernal regions surrounds them, but encompass themselves with smoke of their own accord, and drink a poison which God made black, that it might bear the devil's colour."

COFFIN. Coffins were used by the ancients only to receive the bodies of persons of the highest distinction. Even at the present time, they are not used in the East, either by Mohammedans or Christians. The modern Jews do not use coffins, but only two boards, between which the corpse is tied. But in Egypt, coffins seem to have been used in ancient times universally. They were of stone, wood, or a kind of pasteboard made by gluing cloth together.

Coffins among Christians were probably introduced with the custom of burying. It has been often proposed that they should be made with a hole opposite the place of the mouth of the body, so as to allow breathing, in case of revival. Of course it would be necessary, at the same time, to let the coffin stand for some days in a convenient place, as is the custom in many parts of Germany.

Cohesion is that force which preserves in union particles of a similar kind. Its action is seen in a solid mass of matter, the parts of which cohere with a certain force which resists any mechanical action that would tend to separate them. In different bodies, it is exerted with different degrees of strength, and is measured by the force necessary to pull them asunder. According to Sickingen, the relative cohesive strength of the metals is as follows:

Gold	150,955
Silver	190,771
Platina	262,361
Copper	304,696
Soft iron	362,927
Hard iron	559,880

Cohesion in liquids is very much weaker, the parts being disjoined with much more facility; and, in substances existing in the aerial form, it is entirely overcome, the particles, instead of attracting, repeling each other.

Cohesion in bodies is weakened or overcome by two general causes—by the repulsion communicated by caloric, or by the attraction which may be exerted by the particles of one body on those of another.—Caloric communicated to a solid body separates its particles to greater distances, as is evident from the enlargement of volume which it produces. By thus increasing the distances, the force with which the attraction of aggregation or cohesion is exerted is diminished; if the heat be carried to a sufficient extent, the cohesion is so far weakened, that the body passes into the liquid form; and, if carried still farther, the attractive force is entirely overcome, repulsion is established between the particles, and the body passes into the aeriform state.

Coining. This subject is intimately connected with the value of *money* as a branch of commerce: but to render our view of the matter clear and methodical, it may be advisable to separate the mechanical manufacture of coin from its use as a circulating medium. The latter portion of the subject will be found under Money. Mr. B. Cook has taken some pains to trace the early history of money, and he states in a paper inserted in the *Journal of Science*, that the Scythians were the first inventors of coined money. The most ancient money struck in Greece is easily known, from the method used in making it, because it has *no reverse;* it appears, they found a difficulty in fixing the coin firmly in the die to receive the stroke of the hammer; to effect this, they left upon the reverse several elevations, which entered into the plate or matrix, to prevent it from slipping. These points or elevations were numerous in the first monies, but in time, this rude method was exchanged for a surface a little convex, which served to hold the coin, while the obverse was struck upon it. Upon coins now existing of Syracuse and India, this method is evident.

It appears that the first Greek monies which had any inscription on the reverse, were cut in after the coin had been struck. The obverse was struck first, and then the coin was put in another die, and struck again, with a reverse; and this method appears to have been generally adopted by the people of Japan, as well as Greece.

Some of the first medals of Greece had, for a reverse, the head of Apollo, with his lyre; thus upon the medals of Crete, the head of Apollo appears, who was one of the deities worshipped there; and because Minos pretended to be descended from Jupiter, he was an object of the highest adoration. Idomeneus, who fought at the Trojan war, also attributed his birth to Apollo, the god of day; the eagle, also, is found on the Cretan coins.

A great quantity of coins and medals of Athens, and other cities, were square; and indeed, all over Asia and Africa, there circulated not only square money, but octagon money. There also existed in France, in the time of the Emperor Honorius, a square money, made of red copper, upon the reverse of which was struck the figure of the goddess *Moneta*, with the legend *Exacium Solidi*, weighing about four penny-weights; the form of this money was like the money of Athens.

Upon the money of Thrace we find the head of Apollo, and on the reverse, a griffin; also on some of their medals is represented Jupiter, with an eagle on his hand, and a sceptre; on the medals of Macedonia is represented a horse; upon the medals of Corinth, the face of Minerva is represented, and on the reverse, the *Pegasus*.

The medals of the island of Cos, the birth-place of Appelles and Hippocrates, had the head of Hercules, and on the reverse, the figure of a crab.

There was struck a money of a parallelogram shape, at Pæstum, with a Latin inscription, which proves the time it was made; this ancient Greek city was forced to receive a Roman colony, 465 years after the foundation of Rome, and 289 years before Christ; these Latin medals could not have been struck before this period, which was more than 40 years after the death of Alexander. The square money is never found among the Roman coins, as the severe spirit that called into existence science and arts at Rome, appears under a different shape to that sublime spirit that gave existence to the everlasting inventions of Greece. If, then, any coins of this shape are found with a Roman legend on them, it is certain they were struck in Greece.

If we seek for authority from Plutarch, he says, that Theseus struck the figure of the bull upon the Athenian money, either in honour of his having conquered the bull of Marathon, or, what is more probable, as an emblem of the deity worshipped at Athens; at all events, money with this figure upon it, was used in Athens before the war of Troy; for his successor, *Ménesthée*, commanded the Athenians at that celebrated siege. It was on account of the figure of a bull being struck upon this money, that it was called by the name of this animal.

Upon the medals of *Pandosia* (a city of Greece, now destroyed) is the same impression, which was famous in history, for the defeat and death of Alexander, king of Epirus, who was killed near to its walls, in the same year that the foundation of Alexandria in Egypt was laid. Now, two of the sons of Theseus fought under Agamemnon at the siege of Troy, and leading there the Athenian youth—a city of the greatest influence among the other states—it

is very likely that the money of their father and others, as well as of other states, which had the same impression, was the money then used by the Greeks, both in gold, silver, and brass; for we find that Homer, in speaking of the arms of *Glaucus*, exchanged for those of Diomede, says, that the golden arms of Glaucus were valued at a hundred oxen or bulls; and those of brass, of Diomede, were only valued at nine oxen. *Iliad*, l. 6, v. 235.

It is very certain it could not be animals that were exchanged as money, but money called by this name; so that in 2000 years hence, when the money of this country is described as *sovereigns*, it will not be supposed that sovereigns, mighty men, kings, were in such plenty, as to be used in making exchanges for things to supply our wants, necessities, or luxuries.

It was about the time of Servius Tullius, that the coins of Rome began to take a different figure; the first coins were cast in moulds, with the figures on them very much raised, and rude, and after being made, were adjusted to a certain weight, to correct the errors of casting. These first monies were chiefly of lead; but Numa began to make money of copper, and introduced other designs on it, as all the former coins had only the double head of Janus on one side, with a ship or prow of a vessel on the other.

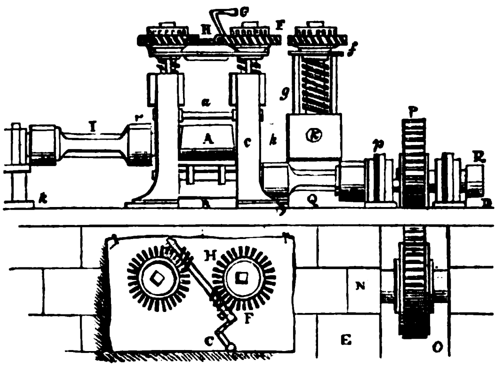
On some medals of *Commodus*, the Supreme Deity is represented under the form of a bull, as indicative of his supreme power. On the reverse of some of the medals of Marcus Aurelius are seen the bull and serpent. On the medals of Persia, and in the works of Zoroaster, this worship was practised. He represents God under the figure of the serpent, and describes him as "the Master of all things—exempt from death—eternal in his duration—without beginning, and without parts."

On the medals of Tartary we find the figure of the serpent; on the reverse of a medal of Tyre we find the serpent encircling an egg; and we find the same figure on the medals of Japan, who, in their cosmogony, say it was the warm breath of the serpent that called into life the first man. In the cosmogony of Phœnicia, *Sanchoniathon* describes "*the first beings as being awakened by a voice of thunder, which spoke to them, calling them male and female on the earth and in the sea; and they began to move.*"

Passing, however, from the ancient coinage to that which relates to our own times, we find a most extraordinary change in the value and execution both of coins and medals effected by the improvements which have taken place in machinery. Copper money manufactured at Birmingham is now equal in point of execution to that of much of the finest gold coinage, without incurring one thousandth part of the expense. Under the article MEDAL we propose giving a history of those splendid specimens of art produced under the patronage of Napoleon, as well as the exquisite medals of Wyon in our own country; and we now proceed to describe the apparatus by which the form is communicated both to coins and medals.

The first process is that of *flatting*, or laminating in the rolling-mill. When silver is to be coined, the bars, before they are passed between the rollers, are heated to redness, which tends to soften them. This is effected in a reverberatory furnace.

When bars of gold are subjected to the same process, they are rolled in a cold state, and a bar of an inch thick can be reduced to that of a half sovereign, without being annealed, and could be made much thinner if necessary, and yet not show the least symptom of cracking.



The above engraving is an elevation of one pair of rollers, and a part of the wheel-work for giving motion to them. A is the upper and B the lower roller; C, the standards, or cast-iron frame which supports them. Each of the standards has an opening in it to receive the bearing brasses for the pivots of the rollers. The upper roller is suspended in brasses, which are regulated by the large screws, F, which admit of placing the rollers at a greater or less distance asunder. In the end view, *h* represents one of the brasses, and *k*, the hole to receive the pivot of the roller. On the upper part of the screw a collar, *f*, is fitted; and from this, two bolts, *g*, *g*, descend and are fastened to the brasses, *h*, with nuts beneath. By these the roller is suspended; but, by turning the screw round, the brasses rise or fall; the brasses are fitted very accurately into the grooves or openings in the standards, C, C.

For the convenience of turning both screws round together, each has a toothed wheel, F, fixed on the upper end of it. These are turned by worms, H, H, fixed on a common axis, which has a handle, G, in front: by turning this handle, the upper roller is either raised or lowered, as is required, but will always be parallel to the lower one. The horizontal view of this apparatus is shown beneath. The two standards are firmly bolted down to the ground sill, which is of cast iron, and bedded in the masonry, E, beneath. The standards are farther united by bolts. At the upper part is a cross-bar fixed between the standards, to support a small table or platform, on which the metal is placed when it is to be presented to the rollers.

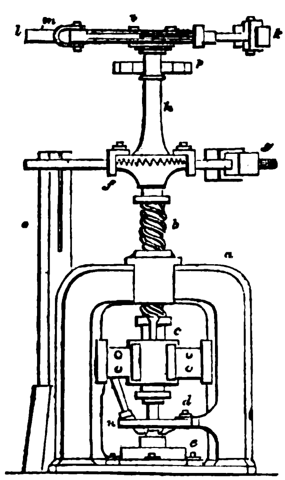
The rollers are put in motion by a steam-engine. The crank of the engine has a toothed wheel upon it which turns a pinion. Upon the axis of this is a very heavy fly-wheel, which turns with great velocity. On the end of the same axis is a pinion, which turns a large wheel, and this gives motion to the shaft, N, which extends beneath the rollers, and is continued a sufficient distance in the same direction to turn two pairs of rollers, one of which only is represented in the engraving at I, and supported by the standard, *k*. A wheel is fixed on this shaft to turn the upper roller, and its axis is connected with a short shaft, with the square on the end of the

roller. The wheel P, is fixed on the shaft, R, to turn the lower rollers by means of the wheel O.

There is also a gauge to ascertain the thickness of the plates, which are reduced by the operation of the rollers; it consists of two steel rulers, fixed fast together at one end, and the other end is a certain distance asunder, forming an opening between them, which gradually diminishes to nothing: the sides of the rulers are divided. In using this gauge to determine the thickness of a piece of plate, the edge of the plate is applied to the opening between the rulers, and the divisions of the rulers show the distance it will go into the opening before it fits tight; and the thickness is ascertained by the number of the divisions.

The plates of metal which have thus been rolled to the required thickness, are then cut into the required width, dependent on the coin to be struck from them. The metal is afterwards still farther adjusted for thickness, either by a second rolling, or by a straw bench, which is similar in its effects. The slips of metal produced from this machine are considerably more uniform in thickness than when finished at the first pair of rollers; consequently the individual pieces are made more nearly to the standard weight, which was the object in view in this invention. When the pieces cut from slips of metal prepared by the drawing-machine, are counted and weighed, which is telling the number of pieces in a pound troy, sovereigns, or half-sovereigns, the variations from standard, either way, seldom exceed three grains troy. It is reckoned good work from the adjusting rollers when the variations are under six troy grains.

The plates of metal prepared by the adjusting rollers, or the drawing-machine, are cut out into circular pieces, of nearly the size of the intended coin. This



is done by the cutting-press, of which *a* is a cast-iron frame, which is fixed on a stone basement; *b* is the screw, which is fitted through the top of the frame, and actuates a slider, *c*. At the lower end of the slider a steel punch, *d*, is fixed. Its diameter is exactly equal to that of the pieces which are to be cut out. Beneath is the steel die, which has a hole in it of proper size to fit the steel punch; on the other side is a box with screws for adjusting the die, so that the hole in it will be exactly beneath the punch. The slide, *c*, is fitted into a socket, which guides it so that it will descend correctly into the hole in the die; *n* is a piece of iron which is fixed a small distance above the die; it has a hole through to admit the punch. Its use is to hold down the piece of metal when the punch rises, otherwise the piece would stick to the punch.

On the upper end of the screw a piece, *f*, is fixed, and an arm projects from it with a weight, *g*, at the end; and it is this weight which gives the necessary momentum to punch out the piece; *h* is a spindle fixed upon the piece, *f*, in the line of the screw; it is supported in a collar, *p*, at the upper end, and above the collar, a lever, *i*, *m*, *k*, is fixed, and at one extremity of this lever a roller, *k*, is placed, and this is acted upon by projecting teeth, which are fixed in the rim of a large horizontal wheel, which is turned round by the power of the mill, and thus produces the requisite motion in the whole apparatus.

The blanks, after being cut to the required size, are examined and then filed to the exact weight. They are then passed through the fire and milled on the edge; the latter process being effected by two saw-like bars of steel, between which the coin is rolled.

The last process to be noticed is that of stamping, which is performed with a screw-press, and the momentum of two heavy weights acting on a punch is employed to form the impression.

The punch or die is formed of steel, and cut with the required figure on the surface, partly by graving tools, and partly by small steel chisels. It is afterwards hardened, and if this part of the process be well performed, will strike many thousand pieces of money.

Coke. Since writing our article Carbon, we have been favoured by the perusal of a memoir on the calcination of coke, which has been furnished for the French government by Messrs. Perdonnet and Leon Coste.

Coke is obtained in England by two distinct processes; in the open air, and by means of ovens constructed for the purpose. The former is the method usually adopted, the latter being applied almost exclusively to the small coal or slack. In the vicinity of Dudley, in Staffordshire, all the coke is made in open air; the process consists in forming a small conical chimney, with bricks placed in such manner as to leave spaces between them; these openings are larger in the lower than in the upper courses; the usual height is about four feet six inches, surmounted by a cylinder of one foot. The coal is then disposed around the chimney, the largest lumps being placed first to form the base of a cone, after which more is thrown on the heap, until the top is above the level of the brickwork; the whole surface is then covered with slack, with the exception of the lowest part of the heap, to about one foot high; the fire is then lighted in the chimney; at a certain period of the operation the remaining part is also covered with slack, and when the carbonization is judged to be complete, the fire is extinguished, by throwing on a sufficient quantity of water and dispersing the materials of the heap.

The dimensions of the coke heaps vary considerably; they are most commonly fourteen or sixteen feet in diameter, and contain about twelve ton of coals. From the time of lighting the pile the operation is completed in seven days, three for the calcina-

tion, and four for the extinction and subsequent cooling of the mass.

It would appear that a method so simple as this would be invariable in the results; nevertheless the contrary is the fact, much depending on the attention and judgment of the burner or superintendant. A ton of coal usually yields twelve cwt. of coke, or sixty per cent., sometimes ten cwt., or fifty per cent. from the same materials. In South Wales both methods are practised, but the coke is not calcined with so much attention as in Staffordshire: the process differs in the heap being made in the form of a long bank four to six feet in breadth, and about three feet high; the large coals in the middle, and the fire being lighted either at one end or at several parts of the heap. At Pontypool and Abergavenny the coke is calcined in the open air; the coal in some parts of this district bears a resemblance to charcoal; in converting it into coke, great care is taken to preserve this entire; the operation is completed in five days. In the neighbourhood of Merthyr Tydvil the process is conducted in the open air, and although very little care seems to be given to its progress, yet a considerable quantity of coke is produced, the coal being generally dry, and giving but little smoke. At Plymouth works six tons of coal yield five tons of coke; at Dowlay 720lbs. of coal yield from 450 to 500lbs. of coke; at Pen-y-Darran, the operation lasts only three days, the increase in bulk being also very considerable, three tons of coal producing twelve barrows of coke, each containing seventeen cubic feet, or above one-fourth part more than previous to calcination.

At Neath Abbey the carbonization is more rapid than in any other place, it being finished in nine hours, producing rather less than sixty per cent. of coke. In Scotland, calcination in the open air is generally adopted; formerly the heaps were burned without much attention being paid to their progress; but the Staffordshire mode has been used latterly with great advantage, the heaps consisting of eighteen tons of coal, well covered with slack, kept burning three or four days, and four or five days more being allowed for the cooling of the mass; the loss in weight is about fifty per cent.; the old method occupied only five days, but the loss amounted to from sixty to sixty-six per cent. The coke is of very unequal quality, some parts being very heavy, and others light and porous. In Yorkshire the coal is arranged in long banks, six feet wide by two and a half high, with square vertical chimneys, eight or nine inches in diameter, formed with large coals, at about the distance of six feet from each other throughout the length; the loss is about fifty per cent. in weight.

Calcination in ovens is considered to produce a heavier coke than the open calcination; the process varies but little, being in all cases performed in ovens of a circular or oval form, with a low arch surmounted with a small chimney; the furnace has two doors or openings opposite to each other, sliding in a groove and raised by a lever; they are usually of cast iron; the dimension of the furnace about twelve feet by six; height of the arch in the centre five feet, at the door twenty-one inches; the chimney is eighteen inches externally, and about nine inches in diameter. At Neath Abbey the furnaces are smaller; the chimney is 18 inches externally, and only one door; but in this case a hole is made in the opposite side to facilitate the clearing out of the coke. From the small coal carbonized in this manner the produce is about sixty per cent., while the same quantity of coal in the open air yields but fifty per cent., the coke from the furnace being so much more dense. At Swansea, by the same process, the produce is about fifty-four per cent.

In the vicinity of Glasgow a circular oven with one door is in use; the diameter is nine feet, height of the arch six feet. The coke is drawn out every twenty-four hours; the ordinary charge, one ton and a half of coal, rising about two and a half feet in the oven; the loss is from fifty to sixty per cent. On Saturdays the charge is increased to two tons, and is not withdrawn until the Monday. At the Lymington works, near Newcastle-upon-Tyne, all the coke is made in ovens; the usual charge is one chaldron of about two and a half tons; the operation lasts forty-eight hours, and the average loss thirty-nine per cent. The coke is screened to the diameter of about one inch for smelting in the high furnace, the smaller portion being employed in roasting the ores. At Bradford, in Yorkshire, the method is similar to Newcastle, but the furnaces are smaller, the charge being only about one ton; the loss is about 40 per cent. It is difficult to decide to which process a preference ought to be given; the loss is less in the ovens, but they require more space, more attendants, and more expense, while the open carbonization is considered to yield coke better adapted for smelting in the high furnace.

Colchicum, or Meadow Saffron, has of late years become quite celebrated as a remedy for that bane of a luxurious life, the gout. It is a very powerful remedy, and should never be used without the attendance and advice of a well-educated medical practitioner, as its effects might otherwise be highly injurious. It is now believed to be identical with the base of the *eau médicinale*, which has been, for so long a period, a celebrated empirical remedy for the gout. It is used in various forms, either the powdered root, or vinegar or wine in which it has been steeped, or, which is considered the best, wine in which the fresh seeds have been steeped. It is also used with benefit in many cases of rheumatic affections, which often so much resemble the gout.

Colcothar is an impure brownish-red oxide of iron, which remains after the distillation of the acid from the sulphate of iron. It forms a durable colour, but is most used by artists in polishing glass and metals.

Cold. All temperature is comparative, and as such but little can be understood of the philosophical character of this subject till we come to the article Thermometer. But the effects of cold are so peculiar, and the phenomena of a diminished temperature in the warmer seasons of the year so important to domestic comfort, that it is advisable to devote a page to the subject.

The Moors introduced into Spain a sort of unglazed earthen jugs, named bucaros, or alcarrazas, which, being filled water, present to the atmosphere a surface constantly humid, and furnish by evaporation, during the dry and hot weather, a refreshing beverage. The same practice has been adopted by degrees in various parts of the south of Europe. In India, the apartments are kept comparatively cool by dashing water against the matting suspended round the walls.

The natives of India, likewise, are enabled, by directing a skilful process of evaporation, to secure for themselves a supply of ice during their short

winter. In the upper country, not far, indeed, from Calcutta, a large open plain being selected, three or four excavations are made in it about thirty feet square and two feet deep, and the bottom covered to the thickness of nearly a foot with sugar-canes, or dried stalks of Indian corn. On this bed are placed rows of small unglazed earthen pans, about an inch and a quarter deep, and extremely porous. In the dusk of the evening, during the months of December, January, and February, these are filled with soft water, previously boiled and suffered to cool, and when the weather is very fine and clear, a great part of the water becomes frozen during the night. The pans are regularly visited at sun-rise, and their contents thrown into baskets which retain the ice. These are now carried to a conservatory made by sinking a pit fourteen or fifteen feet deep, lined with straw, under a layer of coarse blanketing. The small sheets of ice are thrown down into the cavity, and rammed into a solid mass. The mouth of the pit is then closed up with straw and blankets, and sheltered by a thatched roof, so that the ice is readily preserved.

From the above observations it will be seen that a reduction of temperature always accompanies a rapid evaporation. But there are chemical processes for accomplishing the same object, which must be noticed. It consists in the use of a frigorific mixture, the ingredients for which will be best understood by reference to the two following tables:—

TABLE I.

Consisting of Frigorific Mixtures, having the power of generating or creating Cold, without the aid of Ice, sufficient for all useful and philosophical purposes, in any part of the world, at any season.

FRIGORIFIC MIXTURES WITHOUT ICE.

Mixtures.	Thermometer sinks.	Degree of cold produced.
Muriate of ammonia 5 parts. Nitrate of potash . . 5 .. Water. . . . . . 16 ..	From + 50° to + 10°.	40
Muriate of ammonia 5 parts. Nitrate of potash . . 5 .. Sulphate of soda . . 8 .. Water. . . . . . 16 ..	From + 50° to + 4°.	46
Nitrate of ammonia . 1 part. Water . . . . . 1 ..	From + 50° to + 4°.	46
Nitrate of ammonia . 1 part. Carbonate of soda . 1 .. Water . . . . . 1 ..	From + 50° to — 7°.	57
Sulphate of soda . . 3 parts. Diluted nitric acid . 2 ..	From + 50° to — 3°.	53
Sulphate of soda . . 6 parts. Muriate of ammonia 4 .. Nitrate of potash . . 2 .. Diluted nitric acid . 4 ..	From + 50° to — 10°.	60
Sulphate of soda . . 6 parts. Nitrate of ammonia . 5 .. Diluted nitric acid . 4 ..	From + 50° to — 14°.	64
Phosphate of soda . 9 parts. Diluted nitric acid . 4 ..	From + 50° to — 12°.	62
Phosphate of soda . 9 parts. Nitrate of ammonia 6 .. Diluted nitric acid . 4 ..	From + 50° to — 21°.	71
Sulphate of soda . . 8 parts. Muriatic acid . . . 5 ..	From + 50° to 0°.	50
Sulphate of soda . . 5 parts. Diluted sulphuric acid 4 ..	From + 50° to + 3°.	47

TABLE II.

Consisting of Frigorific Mixtures, composed of Ice with Chemical Salts and Acids.

FRIGORIFIC MIXTURES WITH ICE.

Mixtures.	Thermometer sinks.		Degree of cold produced.
Snow, or pounded ice 2 parts. Muriate of soda . . 1 ..	From any temperature	to — 5°.	—
Snow, or pounded ice 5 parts. Muriate of soda . . 2 .. Muriate of ammonia 1 ..		to — 12°.	—
Snow, or pounded ice 24 parts. Muriate of soda . . 10 .. Muriate of ammonia 5 .. Nitrate of potash . . 5 ..		to — 18°.	—
Snow, or pounded ice 12 parts. Muriate of soda . . 5 .. Nitrate of ammonia . 5 ..		to — 25°.	—
Snow . . . . . . 3 parts. Diluted sulphuric acid 2 ..	From + 32° to — 23°.		55
Snow . . . . . . 8 parts. Muriatic acid . . . 5 ..	From + 32° to — 27°.		59
Snow . . . . . . 7 parts. Diluted nitric acid . 4 ..	From + 32° to — 30°.		62
Snow . . . . . . 4 parts. Muriate of lime . . 5 ..	From + 32° to — 40°.		72
Snow . . . . . . 2 parts. Chryst. muriate of lime 3 ..	From + 32° to — 50°.		82
Snow . . . . . . 3 parts. Potash . . . . . . 4 ..	From + 32° to — 51°.		83

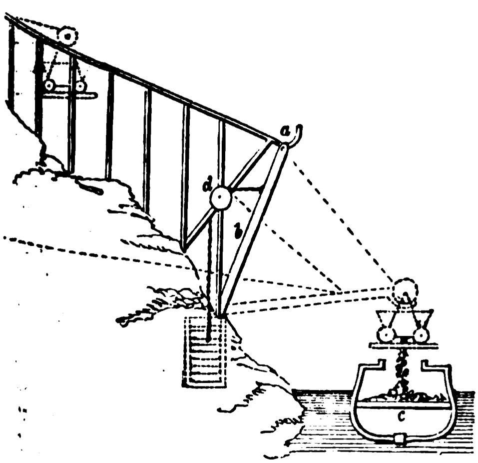
COLIC. The appellation of *colic* is commonly given to all pains in the abdomen, almost indiscriminately; but, from the different causes and circumstances of this disorder, it is differently denominated. When the pain is accompanied with a vomiting of bile, or with obstinate costiveness, it is called a *bilious colic*; if *flatus* causes the pain, that is, if attended with temporary distention, relieved by the discharge of wind, it takes the name of *flatulent* or *windy colic*, when accompanied with heat and inflammation, it takes the name of *inflammatory colic*, or *enteritis*. When the disease arises to a violent height, and is attended with obstinate costiveness, and an evacuation of fæces by the mouth, it is called *passio iliaca*, or *iliac passion*.

Dr. Cullen enumerates seven species of colic. One of the most important is the *colica pictonum*. This is called, from the places where it is endemial, the *Poictou*, the *Surinam*, the *Devonshire colic*; from its victims, the *plumbers'* and the *painters' colic*; from its symptoms, the *dry stomach-ache*, the *nervous* and *spasmodic colic*. It has been attributed to the poison of lead, and this is undoubtedly the cause, when it occurs to glaziers, painters, and those employed in lead works; but, though this is one, it is by no means the only cause. In Devonshire, it certainly more often arises from the early cider, made of harsh, unripe fruit, and in the West Indies from new rum. The characteristics of this disease are, obstinate costiveness, with a vomiting of an acrid or quorraceous bile, pains about the region of the navel, shooting from thence to each side with excessive violence, strong convulsive spasms in the intestines, and a tendency to a paralysis of the extremities.

It is occasioned by long-continued costiveness; by

an accumulation of acrid bile; by cold applied either to the extremities or to the belly itself; by a free use of unripe fruits, and by great irregularity in the mode of living. From its occurring frequently in Devonshire and other cider countries, it has been supposed to arise from an impregnation of lead received into the stomach; but this seems to be a mistake, as it is a very prevalent disease in the West Indies likewise, where no cider is made, and where there is only a very small quantity of lead in the mills employed to extract the juice from the sugar-canes. One or other of the causes just enumerated may justly be said always to give rise to this species of colic. The dry stomach-ache is always attended with some degree of danger, which is in proportion to the violence of the symptoms and the duration of the disease. Even when it does not prove fatal, it is too apt to terminate in palsy, and to leave behind it contractions of the hands and feet, with an inability in their muscles to perform their office; and in this miserable state of existence the patient lingers out many wretched years.

Collier; a vessel much employed for the conveyance of coal from the mining districts, to the London and other great markets. We particularly notice the collier to describe a very improved mode of loading that species of vessel exhibited in the diagram beneath.



On the top of the rail, *a*, which forms part of the staith, the laden carriage is seen descending from the higher level, and when it attains the point *a*, the whole frame, *b*, with the carriage, is lowered down by the chain passing over the pulley at *d*, into the centre of the deck of the vessel, and the coals are received in the hold, at *c*.

Colonel; the commander of a regiment, whether of horse, foot, or artillery. There were times when, in some armies of the European continent, regiments were commanded by generals; but this is no longer the case.

Colonnade; a series or row of columns. Colonnades are of various forms and dimensions, and assume different names according to their application and uses. When in front of a building, or in the interior of a quadrangle, they are called *porticoes;* when surrounding a building of any shape, *peristyles;* when double or more, as in some of the ancient temples and the circular peristyle in front of St. Peter's at Rome, they are *polystyle*. Of this splendid work we give an engraving.

No people have made more use of colonnades, or with greater effect, than the ancient Egyptians; many of their temples being literally thick set, both in the interior and exterior, with colonnades of every description. The Greeks were more simple in their arrangement, and their colonnades were mostly distributed into porticoes and peristyles, both monostyle and polystyle. Their most magnificent example is, perhaps, the temple of Jupiter Olympius, at Athens. Balbec and Palmyra present also various examples of splendid colonnades. Of modern works, the magnificent colonnade of the Piazzo di San Pietro, at Rome, the work of Bernini, is at once the grandest and most beautiful. It consists of two hundred and eighty columns, and forty-eight pilasters, of forty feet high, raised on three lofty steps. It is surmounted by a balustrade, on which are eighty-eight colossal statues of saints, fifteen feet in height. The screen of columns which formerly stood in the front of Carlton Palace, might be cited as an example of one of the most tasteful arrangements of the kind in our own metropolis.

Colour. Colour is a property of light, the knowledge of which can be gained from no description, but is acquired by means of the organ of sight. Colouring substances, or paints, often improperly termed *colours*, are made use of to impart a colour to other substances, either by application or admixture. White and black are counted among colours in the latter sense, but not at all, or seldom in the former, in which sense a white body is very properly called *colourless*. Black is merely the absence of all light.

Colours, both alone and united, have different properties, and produce different effects upon the organs of sense, by means of their harmony or contrast, which are particularly important to painters, and are properties arising from the nervous sensibility. Thus, scarlet is a burning colour, injurious to the eyes; and it is probably on this account that beasts are so violently excited by it. Yellow is the brightest, red the warmest, deep brown and violet the softest among colours. The passing of one colour into another, by mixture, has been displayed in tables, pyramids, &c., for the use of the painter, the colourer, the mineralogist, &c.; but it requires constant familiarity with colours, to make upon the mind impressions sufficiently deep to enable us to distinguish these fine shades of colour with correctness.

Colours, Doctrine of. The doctrine of colours in a general sense, is the science of the origin, the mix-

ture and effects of colour, as a property of light. How, for instance, is it, that light at one time is coloured, at another white? and by what laws are the appearances of colours governed? The glass prism was the first contrivance that gave a satisfactory solution of these questions. If a ray of light is allowed to pass into a dark room through a small opening in a shutter, and is made also to pass through a smooth three-sided glass prism, we find, first, that the ray of light, at its entrance into, and at its passage out of, the glass, is turned from its direct course; it is said to be refracted into a different direction; secondly, that the ray of light, which falling directly upon a piece of paper before the prism, produces a round white spot, produces, when the paper is held behind the prism, a coloured figure, about five times as long as it is wide, and exhibiting the colours of the rainbow, arranged in the same order as they are seen in that phenomenon. This figure or appearance is called the *prismatic spectrum*. The length of it is found to be in a direction perpendicular to the axis of the prism. It is red at the end which is nearest to the refracting angle of the prism, and violet at the end most remote from it, while orange, yellow, green, blue, and indigo follow each other in the intervening space.

Newton concluded from this, and a great variety of similar experiments, that these coloured rays are the simple rays of light, and that white light is composed of the union of them all, according to the relations which they exhibit in the prismatic spectrum. Every white ray of light, therefore, contains all the coloured rays united; but they are not recognized by us, since they produce upon the retina, where they are thus united, the impression we term *white*.

These coloured rays are reflected from all bodies according to similar laws, so that reflected white light is still white; but they are refrangible in different degrees; this property being least in the red rays, moderate in the green, and in the greatest degree in the violet; and they are, on this account separated from each other whenever they are refracted; since from their different refrangibility, although they are parallel, when they fall upon the refracting substance, they take different lines of direction in passing through it. They follow each other, in this respect, in the following order: first violet, then indigo, blue, green, yellow, orange, and red. When these same coloured rays are rendered parallel again, and so fall upon the eye, they appear white, as at first.

Most bodies possess the property of fixing or absorbing some of these coloured rays, which fall upon them, and thus only reflect or transmit rays of a particular colour; and upon this property, according to Newton, the colours of all bodies depend. Blue silk, for example, absorbs six coloured rays, and reflects only the blue; and a solution of cochineal transmits only the red, and absorbs all the other rays. All this is confirmed by the experiments with coloured disks revolving rapidly upon a rod, and with the coloured spectrum falling upon coloured bodies. Many changes and improvements in this theory have been made, particularly in regard to the number of simple coloured rays, which some have reduced to three, and others to two.

COLOURING; one of the essential parts of painting. Besides a knowledge of the art of preparing and mixing colours, and the whole mechanical process, from the beginning to the finishing of a picture, which, in the various kinds of painting, varies according to the materials of each, colouring comprehends the knowledge of the laws of light and colours, and all the rules deducible from the observation of their effects in nature, for the use of the artist. This subject has been treated by Leonardo da Vinci, in his work on painting; Lomazzo and Gerard Lairesse, in books on the same subject; Mengs, in his *Praktischer Unterricht;* Goëthe, in his *Farbenlehre*, &c.

The skill of the painter presupposes a natural ability, founded on superior sensibility, viz. the ability to image forth, and in the imitation, to express with characteristic truth, the peculiar substance and colour of any object under the influences of the light and air. To make this imitation successful, an accurate attention to the local tones and tints is requisite. By *local tones* we understand the natural colour of an object as it appears on the spot where it stands, or from the spot where the spectator is supposed to be stationed. In works of art, the natural colour of an object appears always as a local tone, because every object must be regarded from only one point of view; conformably to which the natural colour is modified according to the supposed distance. By *tints* we understand, in a more restricted sense, the gradations of the clear and obscure, which lights and shadows produce on the coloured surface. In no object of art do these modifications and shades exist in greater delicacy and diversity than in the naked human body, which is, consequently, the most difficult subject for a painter. Colouring, in as far as it is an imitation of the colour and character of flesh (the naked body), is called *carnation*.

If, in addition to the accurate coincidence of the natural colours, local tones, and tints of a painting, with its original, the artists hits the expression of the peculiar character of the substance of which the object consists, the colouring is called *true*. But to truth should be joined beauty, which is attained by the harmonious union of all the tones of the painting into one leading tone. The colouring must conform to and promote the object of the painting, as a work of art, and by the harmony of the colours and lights, as well as by the truth of the local colours, and of the individual parts of the subject, constitute one beautiful whole. In the choice of lights and the distribution of colours, the artist should aim, not only at clearness of representation, but at the same time, at the production of a pleasing harmony, which should aid the general impression of the piece. Consequently, *keeping*, and *chiaro scuro* are comprehended in the idea of correct, beautiful colouring.

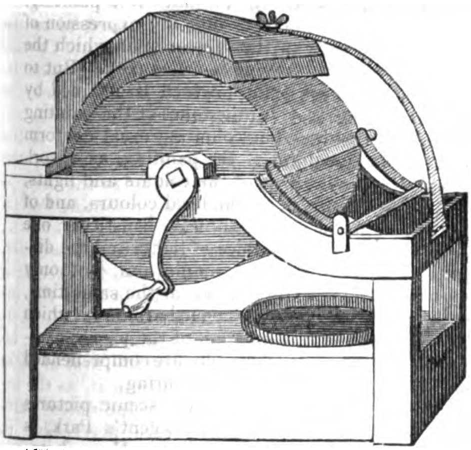
The mode of colouring the great scenic pictures exhibited at the Diorama, in the Regent's Park, is deservedly the subject of admiration. Here, however, the skill of the optician is united to that of the colourist. The light is admitted through various mediums of different tints, and by this ingenious contrivance the accuracy of nature is given to a perfectly flat surface. It may be proper to add, that the varying tints adapt themselves to the character of morning and sunset, and the passage of the clouds is perfectly delineated on the scene.

Colours are earthy and metallic bodies, which require a very intimate blending before they can be employed advantageously by the artist. This is effected both by dry and moist grinding.

The grinding of colours is usually attended with much danger to the labourers employed in that

branch of the process. A mode of diminishing this inconvenience is exhibited in the engraving.

Now, if we suppose the workman to be grinding at the stone beneath, the upward current for carrying off the deleterious vapour, is formed by a fire-place above the hood. A similar process might be advantageously adopted in the pointing of needles; and many other trades. Indeed it is the basis of all scientific ventilation, and has been usefully applied on the large scale in most of our great theatres—the chandelier serving the purpose of a fire-place.



The engraving of the cylindrical mill, represented above, with its hopper, for supplying colour as it is required by the stone, is too simple to need a particular description.

Colossi. The practice of executing statues of colossal dimensions and proportions, is of very high antiquity. The people of the East, from the most ancient times, have been celebrated for colossal sculpture. The pagodas of China and of India, and the excavated caverns of the East, abound with *colossi* of every denomination. The Asiatics, the Egyptians, and in particular the Greeks, have excelled in these works. The celebrated colossus of Rhodes was reckoned one of the seven wonders of the world. This statue, which Muratori reckons among the fables of antiquity, was raised by the Rhodians, in honour of Apollo.

There are many contradictory accounts in ancient authors concerning this colossal statue of Apollo; but the following, gathered from several sources, is not devoid of interest, though mixed up with much fable. When Demetrius, king of Macedon, the son of Antigonus, laid siege to the city of Rhodes, because the Rhodians would not renounce their alliance with Ptolemy Soter, they were succoured by their allies, and particularly by Ptolemy, so effectually, that the besiegers were compelled to abandon their enterprise. The Rhodians, in recognition of their regard for these services of their allies, and of the protection of their tutelary deity, Apollo, resolved to erect a brazen statue of the sun of prodigious size. Chares, the disciple of Lysippus, was intrusted with the project. He had scarcely half finished the work, when he found that he had expended all the money that he had received for the whole, which overwhelmed him so completely with grief and despair, that he hanged himself. Laches, his fellow-countryman, finished the work in the space of three Olympiads (twelve years), and placed the enormous statue on its pedestal. Pliny does not mention the latter artist, but gives all the honour to Chares.

Scarcely sixty years had elapsed before this monster of art was thrown from its place by an earthquake, which broke it off at the knees; and so it remained till the conquest of Rhodes by the Saracens, in A. D. 684, when it was beaten to pieces, and sold to a Jew merchant, who loaded above 900 camels with its spoils. Strabo, Pliny, and other ancient authors, who lived at the time that the colossus of Rhodes is said to have been in existence, and who could have learned from contemporaries the truth or falsehood of the accounts of it, give its height at 70 cubits, or a hundred English feet. Other authors, who flourished since its destruction, report its height at 80 cubits. Pliny also relates other particulars, as that few persons could embrace its thumb, and that its fingers were as long as ordinary statues, which, calculated by the proportion of a well-made man, would make its height nearer to 80 than 70 cubits. Perhaps the latter dimension may relate to its real altitude to the crown of its head, and the greater to its altitude if erect. The statue was placed across the entrance of the harbour, with its feet on two rocks; and the Rhodian vessels could pass under its legs. Some antiquaries have thought, with great justice, that the fine head of the sun, which is stamped upon the Rhodian medals, is a representation of that of the colossus.

One of the largest colossal figures in the world is the *Sphynx*. It is in the midst of a vast ocean of sand, and facing the second great pyramid on the eastern side. Its present appearance is represented beneath.

Sphynxes appear to have been used by the Egyptians, to show the beginning of the waters' rising in

the Nile: with this view, as it had the head of a woman and body of a lion, it signified that the Nile began to swell in the months of July and August, when the sun passes through the signs of Leo and Virgo.

From the deep interest which the Egyptians felt in this mighty river, the hieroglyphical representations in the sphynx were multiplied to a great extent. There is little more than the top of the great sphynx visible, which is more than 100 feet long. It is of one single stone, making part of the rock on which the pyramids are placed. Its head rises about twenty-nine feet above the sand. This, according to Thevenot, is twenty-six feet high, and fifteen feet from the ear to the chin; but Pliny assures us, the head was no less than one hundred and two feet in circumference, and sixty-two feet high from the belly, and that the body was one hundred and forty-three feet long, and was thought to be the sepulchre of king Amasis.

Some have suggested, that the well of the great pyramid led to this monster, and that the priests resorted thither at certain times to pronounce their oracles; alleging that a hole placed at the top of the sphynx's head answered for some deceptive purpose; but this hole is only five feet deep, and communicates neither with the mouth nor with the inside of the colossal monster. The Arabs, who have a holy horror of all representations of men and animals, have disfigured its face with arrows and lances, which has acted much more than time upon the stone.

The learned Mr. Bryant observes, that the sphynx seems to have been originally a vast rock of different strata; which, from a shapeless mass, the Egyptians fashioned into an object of beauty and veneration. It may hardly be necessary to add, that the features are of the Coptic cast.

Of other colossal statues, those which were executed by Phidias are among the most celebrated for beauty and elegance of workmanship. They were his Olympian Jupiter and his Minerva of the Parthenon. The virgin goddess was represented in a noble attitude, 26 cubits or 39 feet in height, erect, clothed in a tunic reaching to the feet. In her hand she brandished a spear, and at her feet lay her buckler and a dragon of admirable execution, supposed to represent Erichthonius. On the middle of her helmet a sphynx was carved, and on each of its sides a griffin. On the ægis were displayed a Medusa's head and a figure of Victory. This colossal work was not only grand and striking in itself, but contained, on its various parts, curious specimens of minute sculpture in *basso rilievo*, which Phidias is said to have brought to perfection.

His Olympian Jupiter was executed after the ungrateful treatment that he received from the Athenians, when he abandoned the city of his birth, which he had rendered celebrated by his works, and took refuge in Elis. Animated rather than subdued by the ingratitude of his countrymen, Phidias laboured to surpass the greatest works with which he had adorned Athens. With this view he framed the statue of Jupiter Olympius for the Eleans, and succeeded even in excelling his own Minerva in the Parthenon. This colossal statue was 60 feet in height, and completely embodied the sublime picture which Homer has given of the mythological monarch of the heavens.

While describing the *colossi* of ancient times, we should not forget the magnificent and extravagant proposal of Dinocrates to Alexander the Great, of forming Mount Athos into a colossus of that conqueror; nor a similar proposal, in modern times, of sculpturing one of the Alps, near the pass of the Simplon, into a resemblance of Napoleon. Among other celebrated *colossi* of ancient times, historians record as eminently beautiful, that which was executed by Lysippus at Tarentum. It was 40 cubits or 60 feet in height. The difficulty of carrying it away, more than moderation in the conqueror, alone prevented Fabius from removing it to Rome, with the statue of Hercules, belonging to the same city. *Colossi* were in use also in Italy before the time when the Romans despoiled their vanquished enemies of their works of art. The Jupiter of Leontium, in Sicily, was 7 cubits in height, and the Apollo of wood that was transported from Etruria, and placed in the palace of Augustus, at Rome, 50 feet.

The same emperor also placed a fine bronze colossus of Apollo in the temple of that god, which he built near his own palace. The earliest colossus recorded to have been sculptured in Rome was the statue of Jupiter Capitolinus, which Spurius Carvilius placed in the capitol after his victory over the Samnites; but *colossi* soon became far from scarce. Five are particularly noticed; namely, two of Apollo, two of Jupiter, and one of the sun. There has been dug up, among the ruins of ancient Rome, a colossal statue of the city of Rome, which was reckoned among the tutelary divinities of the empire. The superb *colossi* on the Monte Cavallo, called by some antiquaries the *Dioscuri*, are magnificent specimens of Grecian art; so are the Farnese Hercules and the gigantic Flora of the Belvedere. It used to be the common opinion, that the *colossi* on Monte Cavallo both represented Alexander taming Bucephalus. They are now generally believed to represent the *Dioscuri* Castor and Pollux; the statue which, according to the inscription on the pedestal, is the work of Phidias, being intended for Castor; the other, of inferior value, and, according to the inscription, the production of Praxiteles, representing Pollux. The original design of these statues is not known; nor does it appear from history what led Praxiteles, after an interval of about 80 years, to execute a counterpart to the work of Phidias, in case the inscription is to be credited. The editors of Winckelmann's works (vi. 2d part, p. 73, and v. p. 560), on account of the elevated character of the first of these statues, think it reasonable to attribute it, as the inscription does, to Phidias; for in the individual parts there is no narrow, laboured care perceptible in the execution, no overwrought polish and elegance. From various inequalities on the statue of the man—for instance, on the chin—they conjecture that this work was not completed by that great master, and hence was not esteemed so highly at first as afterwards, when the era of noble Grecian sculpture had passed away, and when the statue was probably first set up. But, as the primitive design of the work required a counterpart, they conjecture that the sculpture was committed to Praxiteles, the most perfect artist of that period.

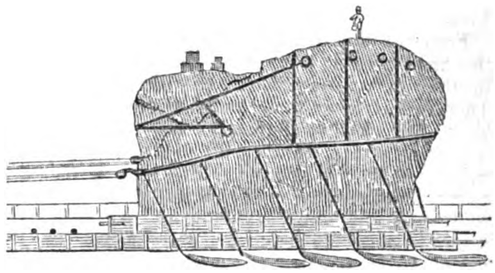
On this hypothesis, they explain the marks of a later age in the second statue, particularly the great dexterity with which the master has imitated the first, and finished every part without seeming to be a

mere copyist. The want of that lofty spirit which distinguishes the earlier statue they ascribe to the constraint of the artist in forming a counterpart to a previous work, and to the circumstance that Praxiteles, belonging to an age which was fond of the gentle and soft, entered the lists with the giant of an earlier period in the arts. Canova has attempted to prove, from the nature of the groups, that in both, the hero and horse were so placed that the two could be seen at once; and perhaps it was so originally; but the horse is now exactly opposite to the spectator, and the whole is less agreeably grouped. Rome possesses several other *colossi*, of admirable workmanship, as the colossal statue of Alexander the Great, in the Colonna palace; the rare colossus of Antoninus, in the Palazzi Vitelleschi; the celebrated statue of the Nile; the four statues that surround the splendid fountain and obelisk of the Piazza Navona, the admired work of Bernini. They are personifications of four of the principal rivers in the world; namely, the Ganges, which was sculptured by Fran. Baratta; the Nile, by Antonio Fancelli; the Danube, by Claude Franc; and the Rio de la Plata, by Antonio Raggi. Other colossal statues of less consequence are also found among the beautiful works of art in this city.

The pride and ambition of the Roman emperors led them to encourage sculptured representations of their persons. Nero was the first who ventured on a colossus of himself, by Zenodorus; but, after his death, it was dedicated to Apollo or the sun. Commodus afterwards took off the head, and replaced it with a portrait of himself. Domitian, actuated by a similar ambition, prepared a colossus of himself as the deity of the sun. Among more modern works of this nature is the enormous colossus of San Carlo Borromeo, at Arona, in the Milanese territory. It is of bronze, 60 feet in height, and has a staircase in its interior, for the purpose of occasional repairs and restorations.

The bronze colossus, copied from one of the Monte Cavallo statues, in Hyde Park, London, and a few but little larger than life, of the size that may be termed *heroic* rather than *colossal*, such as decorate some public buildings and commemorative columns, as those on St. Paul's Cathedral; William Pitt, in Hanover Square; the Duke of Bedford, in Russell Square; Charles Fox, in Bloomsbury Square, &c., are the principal of which we now boast in this noble style of art. The four colossal statues at Paris, which are in front of the façade of the *Corps Législative*, are in good taste, and show great boldness and freedom in the execution. They represent the four greatest legislators of France—Sully, Colbert, L'Hopital, and D'Aguesseau. They are in their proper costume, and seated. Canova's Perseus is also much larger than life, and a very fine work. They belong rather to the heroic than the colossal.

The enormous weight of many of the ancient as well as modern *colossi*, has very materially increased the difficulty of their erection. We may take a single example, namely, that of the statue of Peter the Great at St. Petersburg. The base alone weighed 400,000 lbs., and yet it was transported many miles both by sea and land. In the first of these cases it was conveyed between two frigates, and in the second its transit was accomplished by the aid of friction-balls. The accompanying engraving will give a general notion of the process. Two vast beams grooved to receive the friction-balls were placed beneath each of the sides of the stone, and capstans worked by several men, each were employed to give



motion to the mass. On the top of the stone was placed a drummer, by whose instrument the combined efforts of the men were regulated. The small moveable stages attached by ropes, which are seen in the engraving, were used to convey the workmen and their tools along with the colossal stone.

Columbium. This metal was discovered in 1801, by Mr. Hatchett, who detected it in a black mineral, belonging to the British Museum, which was originally sent to Sir Hans Sloane by Governor Winthrop, of Connecticut, and was supposed to have been found near New London in that state. About two years after M. Ekeberg, a Swedish chemist, extracted the same substance from tantalite and yttro-tantalite, and, on the supposition of its being different from columbium, described it under the name of *tantalum*. The identity of these metals, however, was established in 1809 by Dr. Wollaston.

Columbium exists in its ores as an acid, united either with the oxides of iron, manganese, and tin, as in the columbite or tantalite; or in combination with the earth yttria, as in the yttro-columbite, or yttro-tantalite. This acid is obtained by fusing its ore with three or four times its weight of carbonate of potash, when a soluble columbate of that alkali results, from which columbic acid is precipitated as a white hydrate by acids. When this acid is exposed to the united agency of charcoal and intense heat, it is reduced to the metallic state.

The metal is brittle, of an iron-gray colour, and feebly-metallic lustre. Its specific gravity is 5.6. It is not attacked by the nitric, muriatic, or nitro-muriatic acids, but is converted into the acid by being heated with potash or nitre. Columbium has hitherto been obtained in very minute quantities, and has never been applied to any economical purpose. Columbite, the ore from whence it is obtained, has of late been discovered in several places in New England.

Column (*columna*, Lat.), in architecture, a round pillar. In the earliest periods of the world the column was merely the trunk of a tree, or its imitation in stone, used to support the roof. The parts of a complete column are its *base*, on which it rests, its body, called the *shaft*, and its head, called the *capital*. Columns are used to support the entablature of an order, which has also its proper division. In the most ancient times columns of wood were the most usual, as being the most easily wrought. In countries like Egypt, where timber fit for construction is scarce, and stone abundant, the latter became the principal material for columns; and those of Egypt

are remarkable for the beauty of their workmanship, and the durability of their materials.

The Greeks used marble of the finest kind, with which their country abounded, for their columns; and other nations, the stone or material of their country. The Greeks properly considered the column as an essential part of the architecture of their temples, and never used it as a mere decoration. The manner of constructing the columns of all the orders rests upon similar principles. They are all divided into three primary parts or divisions, the base, the shaft, and the capital, except the Doric order, which has no base. The lowest or thickest part of the shaft is used by architects as the universal scale or standard whence all the measures which regulate and determine heights and projections are taken; and this standard or scale must be understood before any architectural design can be commenced.

The relative proportions of the various species of column has already been given in our article illustrative of general architecture.

We have now to notice the employment of columns as *trophies*. The Romans had their *columna bellica*, which was near the temple of Janus, and from which war was proclaimed by the consul casting a javelin from it towards the country of their enemy; also *chronological columns*, whereon they inscribed historical events according to the order of time.

They had also a *lacteal column*, which was erected in the vegetable market, and contained in its pedestal a receptacle for infants that were abandoned by their parents. The *legal column* was one on which the ancients engraved their laws; the *limitative* or *boundary column* marked the boundary of a state or province; the *manubial column* was ornamented with trophies and spoils taken from the enemy; the *rostral column* with the prows (*rostra*) of the ships obtained in a similar manner. The first column of this description was that which was erected in the capitol, on the occasion of the naval victory which Caius Duilius obtained over the Carthaginians. It is now on the balustrade of the grand staircase of the Campidoglio. Augustus raised four, decorated with the prows of the vessels which were taken from Cleopatra. Two were also erected to the honour of Caius Menius, for a naval victory over the Latins and Antiates.

The *sepulchral column* was elevated upon a sepulchre or tomb, with an epitaph engraved upon its shaft. The *triumphal column* was erected by the Romans in commemoration of a conqueror to whom had been decreed the honours of a triumph. The joints of the stones were concealed by crowns obtained by military conquests. The columns of Trajan and Antonine, besides their specific objects, are also triumphal columns.

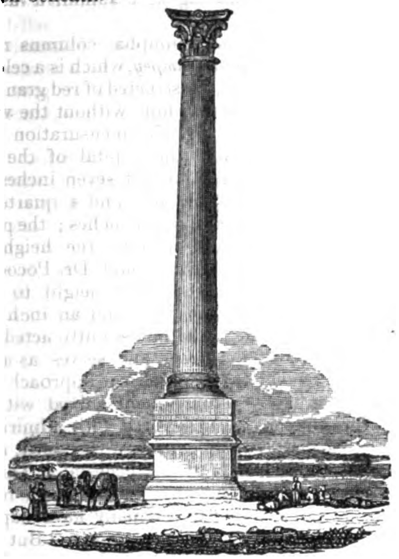
The British Parliament, when they voted the magnificent palace of Blenheim to the great Duke of Marlborough, also erected a triumphal column in the park. On the four sides of the pedestal are inscribed descriptions of the victories of that great commander; and his statue is upon the abacus, supported by figures of captured enemies, and surrounded by trophies.

The *military column*, or *milliarium aureum*, of Rome, was originally a column of white marble, which Augustus erected near the temple of Saturn, in the forum, as a centre whence the account of the miles began in the calculation of distances from the city. This celebrated column is still in existence, being placed on the stylobate in front of the Campidoglio, the modern capitol of Rome. It is a short column, with a Tuscan capital, and has a ball of bronze, as a symbol of the globe. It was called *golden*, either because it was once gilded all over, or at least the globe and ornamental accessories. As a companion to it is a similar column, bearing on its summit a vase, containing the ashes of Trajan.

Among the principal triumphal columns now remaining is the column of *Pompey*, which is a celebrated monument of antiquity, constructed of red granite, and situated on a rock, about a mile without the walls of Alexandria, in Egypt. By the mensuration of Edward Wortley Montagu, the capital of the pillar, which is Corinthian, is nine feet seven inches high; the shaft sixty-six feet one inch and a quarter; the base five feet nine three-quarter inches; the pedestal ten feet five and a half inches; the height from the ground ninety-two feet: though Dr. Pococke, by the shadow, determined the whole height to be 114 feet; and its diameter nine feet and an inch. It is perfectly well polished, and but slightly acted on by time. It overtops the town, and serves as a signal for vessels. Savary says, on a near approach it produces a degree of astonishment mixed with awe. The spectator can never be tired with admiring the beauty of the capital, the length of the shaft, nor the extraordinary simplicity of the pedestal. This prodigious mass stands, as on a pivot, on a reversed obelisk; and was erected, as many have supposed. either by Pompey, or to his honour. But as no mention is made of it by Strabo, Diodorus Siculus, or any other ancient writers, Mr. Montagu concludes that it was not known before the time of Vespasian, and that it was created to his honour. In proof of this opinion, he found within the circumference of the pillar a medal of Vespasian, in fine preservation.

Savary, on the authority of Abulfeda, who calls it "the pillar of Severus," ascribes it to this emperor; alleging that he visited Egypt, gave a senate to Alexandria, and deserved well of its inhabitants. Accordingly, it is said, that this column is a mark of their gratitude. The Greek inscription, now more than half effaced, was, no doubt, legible in the time of Abulfeda, and preserved the name of Severus. Nor is this the only monument erected to him by the gratitude of the Alexandrians. In the midst of the ruins of Antinoe, built by Adrian, is seen a magnificent pillar, the inscription on which is still remaining, dedicated to Alexander Severus. Denon has given a drawing of this pillar, with the marked dimensions of its various parts: it makes its whole height a fraction more than 92 feet, and the height of the shaft, which is of a single piece, 63 feet 1.3. It acquired, as this author says, the name of Pompey's Pillar in the 15th century. A monument, as he supposes, had been raised by Pompey at Alexandria, but it had disappeared, and was thought to be discovered in the above column, which has since been converted into a trophy erected to the memory of Septimius Severus. It is, however, placed on the ruins of the ancient city; and, in the time of Septimius Severus the city of the Ptolemies was not in a ruinous state. If the shaft of this column, continues Denon, once belonged to an ancient edifice, it is an evidence of its magnificence, and of the skill with which it was executed. It ought therefore to be said, that what is called Pompey's Pillar is a fine column, and not a fine monument, and that a column is not a monu-

ment. In consequence of the earth about the foundation of this pillar having been cleared away, two fragments of an obelisk of white marble, the only monument of that substance seen by Denon in Egypt, have been added to the original base, to render it more solid. An engraving of this celebrated column is given beneath.



The *Trajan column* is one of the most celebrated monuments of antiquity. Its height, including the pedestal and statue, is 132 feet. This monumental column was erected in the centre of the forum Trajani, and dedicated to the Emperor Trajan for his decisive victory over the Dacians, as is testified by the inscription on the pedestal. It is of the Doric order, and its shaft is constructed of 34 pieces of Greek marble, joined with cramps of bronze. For elegance of proportion, beauty of style, and for simplicity and dexterity of sculpture, it is the finest in the world. The figures on the pedestal are masterpieces of Roman art. It was formerly surmounted by a statue of Trajan, which has been succeeded by a statue of St. Peter.

The *column of the Emperor Phocas* is near the Temple of Concord. It is of Greek marble, fluted, and of the Corinthian order, four feet diameter, and fifty-four feet high, including the pedestal. The *Antonine column* was erected by the Roman senate to the glory of Marcus Aurelius, for his victories over the Marcomanni, in the reign of Commodus. Aurelius afterwards dedicated it to his father-in-law, Antoninus Pius. According to a rigid admeasurement, made by M. de la Condamine, this column is 116 French feet in height, and 11 in diameter. It is built entirely of marble, and encircled with *bassi rilievi*, which form 20 spirals around its shaft. It has been well illustrated by engravings and descriptions by Pietro Santi Bartoli. It is in every respect inferior to that of Trajan as a work of art, particularly in the style and execution of the sculptures. It was repaired in 1589 by Fontana, under the pontificate of Sixtus V., who placed a colossal statue of St. Paul upon its summit.

There is also in Rome another column bearing the same name, situated on the Monte Cittorio. Its shaft is of a single piece of Egyptian granite, 45 feet in height, and 5 feet eight inches in diameter. Its pedestal is ornamented with *bassi rilievi*, representing the apotheosis of Antoninus and Faustina, and other events relating to the history of Rome. It was repaired by Lambertini. Pius VI. removed the *bassi rilievi* to the Vatican. There is an engraving of it in the 5th volume of the *Museo Pio-Clementino*. On one of its sides it has the following inscription:—"Divo Antonino Avgvstino pio Antoninvs Avgvstvs et Vervs Avgvstvs filii." Till the commencement of the 18th century, there were to be seen at Constantinople two insulated columns, ornamented with *bassi rilievi*, in the style of the Trajan column at Rome. One was erected in honour of Constantine, and the other of Arcadius or Theodosius. Of the latter there is nothing left but its granite base, the column having been destroyed by the Turks. It had been several times damaged by earthquakes, and they were fearful of its falling. The *Constantine column* was composed of seven large cylindrical blocks of porphyry, and was originally surmounted by a statue of Constantine. After having been several times damaged by fire, it was repaired by the Emperor Alexis Comnenus, as is indicated by an inscription in Greek.

The column which ornaments the British metropolis, better known as the *Monument*, was designed by Sir Christopher Wren, and erected by order of parliament, in memory of the burning of the city of London, anno 1666, in the very place where the fire began. This pillar was begun in 1671, and finished in 1677.

It is of the Doric order, fluted, 202 feet high from the ground, and fifteen feet in diameter, of solid Portland stone, with a staircase in the middle, of black marble, containing three hundred and eighty-five steps. The lowest part of the pedestal is 28 feet square, and its altitude 40 feet; the front being enriched with curious *bassi rilievi*. It has a balcony within 32 feet of the top, on which is placed a blazing urn of gilt brass.

The column in *Phœnix Park*, Dublin, differs from any other work of this description. It was erected in 1745. It stands in the centre of an area where four great avenues meet, and from which there are entrances to the Vice-regal Lodge, and that of the chief secretary. The trees which shade the avenues form vistas, through which the perspective view of the column forms a picturesque object.

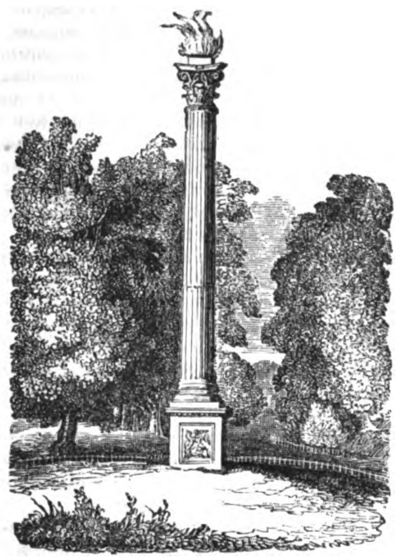
The pillar is formed of Portland stone, and is of the Corinthian order, fluted, and highly ornamented. The base and pedestal five feet in height, the shaft and capital twenty, and the phœnix which surmounts the column five feet, so that the whole presents an object thirty feet high. On the east and west sides of the pedestal are the following inscriptions:—

Civivm Oblectamento
Campvm Rvdem et Incvltvm
Ornari Ivssit
Philippus Stanhope,
Comes de Chesterfield
Prorex.

Impensis svis Posvit
Philippus Stanhope, Comes
De Chesterfield Prorex.

On the north and south sides are the crest and arms of Stanhope in relief. It is to be regretted, that from the perishable nature of the stone, this ornament to the park even already exhibits symptoms

of decay. To protect it from accidental violence, it has been enclosed by a circular iron railing; but this defence, while it keeps off the hand of man, cannot keep off the hand of time, which is fast obliterating its ornaments.



The *Napoleon column* has justly been considered as the greatest ornament of the Parisian capital. It stands in the Place Vendome, and was erected to commemorate the successful result of Bonaparte's arms in the German campaign of 1805.

Its total elevation is 135 feet, and the diameter of its shaft is twelve feet. It is in imitation of the pillar of Trajan at Rome, and is built of stone, covered with bas-reliefs (representing the various victories of the French army), composed of twelve hundred pieces of cannon taken from the Russian and Austrian armies. The bronze employed in this monument was about three hundred and sixty thousand pounds weight. The column is of the Doric order. The bas-reliefs of the pedestal represent the uniforms and weapons of the conquered legions. Above the pedestal are festoons of oak, supported at the four angles by eagles, in bronze, each weighing five hundred pounds. The bas-reliefs of the shaft pursue a spiral direction from the base to the capital, and display in chronological order the principal actions of the campaign, from the departure of the troops from Boulogne to the battle of Austerlitz. The figures are three feet high; their number is said to be two thousand, and the length of the spiral band eight hundred and forty feet. Above the capital is a gallery, which is approached by a winding staircase within, of one hundred and seventy-six steps. It has the following inscription:

Monument élevé a la glorie de la grand armeé.
Par Napoleon Le Grand
Commencé le xxv Août 1806,
Terminé le xv Août 1810.
Sous la direction de D. V. Dénon.
MM. J. B. Lepére et L. Goudoin, architectes.

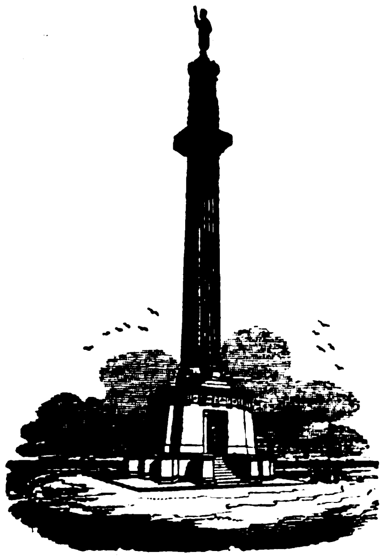
Over the door leading to the staircase is a bas-relief, representing two figures of Fame supporting a tablet.

The capital of the column is surmounted by an acroterium, upon which formerly stood the statue of Napoleon, measuring eleven feet in height, and weighing five thousand and twelve pounds. The platform upon which it rests is of white marble, surmounted with palisades. Some of the most beautiful portions of this column, or rather of its *bas relief* ornaments, were designed by a young and self-taught female artist; a lady who, but for the deposition of Napoleon, would in all probability have attained the highest and most lucrative walks in her profession. The total expense of this sumptuous monument was 1,500,000 livres.

There are also several smaller columns, but of beautiful proportions, in various parts of England, in imitation of the above, but mostly of the Grecian or pure Doric order, as the Anglesea column, erected in commemoration of the battle of Waterloo, and the noble earl of that name, in the island of Anglesea; the column at Shrewsbury, erected in commemoration of the same event, and of another noble general, Lord Hill; the Nelson columns, at Yarmouth and in Dublin; the Wellington column, at Trim, in the county of Meath, Ireland, &c.

To the above list, we may add the *Washington monument*, at Baltimore, on which a colossal statue of Washington has been placed. The pillar is of the Grecian Doric order, and of very massive proportions. It stands on a grand base or zocle, and is surmounted by a circular pedestal, on which the statue rests. This base or zocle of the monument is 50 feet square, and 25 feet high; the column is 20 feet in diameter, and with its sub-base, 130 feet high; the capital is 20 feet square. The statue is 15 feet high, and the whole height of the monument, from the pavement, including the statue, will be 176 feet. As it stands on a hill 100 feet high, this structure rises 276 feet above tide. It is constructed of white marble, which is slightly variegated, and is a very conspicuous object to every one approaching the city, whether by land or water. The statue greatly increases its effect, and gives finish and beauty to the whole structure. A flight of steps, on each side of the grand base, leads up to the door-way. A broad frieze runs round the exterior of the grand base, with a series of civic wreaths, each encircling a star, to designate the states of the Union. In the centre of the frieze, above the door-ways, are large marble tablets, inscribed with the name of Washington. Bronze inscriptions, commemorative of events in the revolution connected with the life of Washington, are placed on every front of the base. The base of the column above the great platform is encircled with thirteen colossal bronze shields, emblematic of the federal union; the faces of the shields are ornamented with the arms of those states which formed the federal compact, divided by massive spears. The attitude given to the statue represents the great man to whom the monument is dedicated in the act of resigning his commission, and the authority with which he had been invested by his country, again into the hands of the people, having accomplished the great object of his appointment—the freedom and independence of the Union. The marble of which the statue is formed is of a very pure kind, free from veins, and is a fine specimen of the native white formation which abounds in the neighbourhood of Baltimore. The statue, the work of Mr. Causici, weighs 16½ tons.

The column erected to the memory of Lord Nelson, on the *Denes*, at Yarmouth, was completed in 1817, and forms a *sea-mark* visible at an immense distance. It is represented beneath.



The following translation of the Latin inscription by Serjeant Frere, will best explain the object of this beautiful column:—

"HORATIO LORD NELSON,

whom, as her first and proudest champion in naval fight, *Britain* honoured, while living, with her favour, and, when lost, with her tears; of whom, signalized by his triumphs in all lands, the *whole earth* stood in awe, on account of the tempered firmness of his counsels, and the undaunted ardour of his courage. This great man *Norfolk* boasts her own, not only as born there of a respectable family, and as there having received his early education, but her own also in talents, manners, and mind. The glory of so great a name, though sure long to outlive all monuments of brass and stone, his fellow-countrymen of Norfolk have resolved to commemorate by this column, erected by their joint contributions. He was born in the year 1758, entered on his profession in 1771, and was concerned in nearly 150 naval engagements with the enemy; being conqueror, among various other occasions, at Aboukir, August, 1798; at Copenhagen, April, 1801; and at Trafalgar, October, 1805; which last victory, the crown of so many glorious achievements, he consecrated by a death equally mournful to his country and honourable to himself."

COLUMN, in *tactics*; a deep, solid mass of troops, formed by placing several bodies of men behind each other (sections, platoons, companies, squadrons, and even several battalions). The column is either an open or a close one (with intervals, or having the sections close behind each other): it may be formed either for marching or for attack. By means of columns, it is possible to march in places where it would be impracticable to move with unbroken lines. They also increase the force and steadiness of troops, both in attack and defence. The drawing up of the infantry in line is advisable, where there is no obstacle in the ground to prevent advancing in this order, or when the enemy is to be received with the fire of musketry, and where cannon-balls and grenades are more to be feared than case-shot and musketry.

Almost all battles are fought, at present, by small columns, which, when the order in line is judged more for the purpose, may be changed into lines, and which, besides, form the best squares for resistance against attacks of cavalry, by presenting a front to all sides, and unite many other advantages. In the case of cavalry, also, attacks may be made either in column or in line. The charge in close columns, which is in use particularly with the French, is of the greatest effect when it succeeds; but when it fails, the whole body of assailants is exposed to annihilation or to rout, as no support, no developement, nor orderly retreat is possible.

The attack with columns at some distance from each other has this advantage, that if the first division fails, the subsequent ones may succeed; moreover, the facility of manœuvring is much greater. This mode of attack is particularly advisable in assaulting squares of infantry. Marching and fighting in lines, however, are the modes usually practised by cavalry.

COMBINATION, in *Mathematics*, is the variation or alteration of any number of figures, letters, colours, sounds, &c., in all the different manners possible. The parts combined are called *elements*.

The *doctrine of combination* is that branch of mathematics which teaches the mode of acquiring the results arising from all possible combinations, and gives rules respecting them.

Combinatory analysis is the application of the doctrine of combination to analysis, and constitutes a branch of science often very involved. A system of characters is appropriated to this purpose. Hindenburg, of Leipsic, in 1778, gave it the character of an independent science; and it has been of important service in relation to the higher branches of mathematics.

COMBUSTION. It is not easy to give a correct definition, or to assign a general cause, of this familiar phenomenon. It may, however, be described as the result of the combination of two or more bodies, attended with a disengagement of heat and light. This description distinguishes *combustion* from *ignition*, which is merely the result of an elevation of the temperature, without any chemical combination. Fire was formerly considered as an element, which had the power of converting certain bodies into its own nature; but the progress of chemical science soon showed the error of this notion. Stahl's celebrated theory was founded on the hypothesis of the existence of a substance which he called *phlogiston*.

Every combustible body was supposed to contain this substance, which was disengaged by combustion: the loss of the phlogiston was the cause of the residuum being incombustible. The heat and light were attributed to the violent agitation of the phlogiston at the moment of its disengagement. The discoveries of Black and Priestley opened the way to the system of Lavoisier, which, in 1785, entirely supplanted the theory of Stahl. During the conversion of solids into fluids, and of fluids into vapours, there is a considerable absorption of heat: when, on the contrary, vapours and liquids are restored to the fluid and solid form, the heat which they contain is evolved, and passes from the latent to the sensible state.

These views were assumed by Lavoisier as the basis of his theory.

Oxygen gas was considered as a compound of a peculiar basis, united to the matter of light and heat, and combustion as the combination of oxygen with the burning body. During the combustion, the basis, combining with the combustible, augmented its weight and changed its properties; while the imponderable elements of the gas—light and heat—were developed in the form of flame. But facts prove this theory incorrect. In the first place, all the phenomena of combustion take place, in many cases, without the presence of oxygen. In the second place, there are many cases in which oxygen unites with bodies, without the evolution of light and heat, as during the change of some metals on exposure to the air. And, farther, there are many instances in which combustion takes place not only without condensation, but where gaseous matter is actually produced from solid matter, as in the inflammation of gunpowder. Besides, the evolution of light, if it were derived from the gas, should be proportional to the quantity solidified, whereas it depends chiefly on the combustible.

The first of these objections to Lavoisier's theory, which is yet generally received, has been partly removed by modifying the definition so as to extend it to several other bodies, hence called *supporters of combustion*. The definition which we have given of this phenomenon at the beginning of this article is merely a description. The question arises, Whence come the light and heat? They are generally referred to the condensation which is almost always a necessary consequence of a chemical combination; but we have already seen that, in some cases, they are produced where the component parts actually pass from a solid to a gaseous state. It seems probable, in the present state of our knowledge, that they may be attributed to the disengagement of the electric fluid. "In every chemical combination," says Berzelius, "there is a neutralization of opposite electricities, and this neutralization produces the heat and light in the same manner as it does in the Leyden jar or the galvanic battery." But to this it may be objected, that if electricity were the cause of the disengagement of the heat and light, they would always bear a fixed proportion to each other. This is not the case: the combustion of oxygen and hydrogen disengages a very great quantity of caloric, but very little light; that of phosphorus and oxygen produces opposite results.

There is, then, no theory of combustion, at present received, which will explain all the circumstances of this phenomenon. If there be any one general cause, it must be one which, like affinity, is modified by the nature of the agents and the peculiar circumstances of their mutual action.

Combustion, Spontaneous. There is no subject connected with the animal economy and the theory of chemical change, which has excited so much attention as the one now before us. Volumes have been written on the subject of spontaneous combustion, and yet we are in possession of no satisfactory theory of its origin. The facts, however, which have been collected, are of so curious a character, as to warrant our preserving some of the best authenticated cases.

We read, in the *Transactions of the Society of Copenhagen*, that, in 1692, a woman of the lower class, who for three years had used liquors to such excess, that she would take no other nourishment, having sat down one evening on a straw chair to sleep, was consumed in the night-time, so that no part of her was found but the skull and the extreme joints of her fingers; "all the rest of her body," says Jacobus, "was reduced to cinders."

In the *Annual Register* for 1763, is published the following memoir by Bianchini: "The Countess Cornelia Bandini, of the town of Cesena, aged 62, enjoyed a good state of health. One evening, having experienced a sort of drowsiness, she retired to bed, and her maid remained with her till she fell fast asleep. Next morning, when the girl entered to awake her mistress, she found nothing but the remains of her body in the most horrid condition. At the distance of four feet from the bed was a heap of ashes, in which could be distinguished the legs and arms untouched. Between the legs lay the head, the brains of which, together with half the posterior part of the cranium remained, but the whole chin had been consumed. Two fingers had been found in the state of a coal, and the rest of the body reduced to ashes, which, when touched, left on the fingers a fat, fetid moisture. A small lamp which stood on the floor was covered with ashes, and had no oil. The tallow of two candles was melted on a table, but the wicks remained untouched, and the feet of the candlesticks were covered with a certain moisture. The bed was not damaged. The bed-clothes and coverlid were raised on one side, as is the case when a person gets up. The furniture and tapestry were covered with a moist soot, the colour of ashes, which had penetrated the drawers and soiled the linen. This soot having been conveyed to a neighbouring kitchen, adhered to the walls and the utensils; a piece of bread in the cupboard was covered with it, and no dog would touch it. The infectious odour had been communicated to other apartments." This account states that the Countess was accustomed to bathe all her body in camphorated spirits of wine.

In the same work, anno 1773, is given an account from Mr. Willman, a surgeon, of the death of Mary Clues, aged 50, who was much addicted to intoxication. "Her propensity to this vice had increased after the death of her husband, which took place a year and a half before. For about a year, scarcely a day had elapsed in which she did not drink half a pint of rum or aniseed. Her health gradually declined; when, about the beginning of February, she was attacked by the jaundice, and confined to her bed. Though she was incapable of much action, and not in a condition to work, she still continued her old habit of drinking every day, and smoking a pipe of tobacco. The bed on which she lay stood parallel to the chimney of the apartment, and at a distance from it of about three feet. On Saturday morning, the 1st of March, she fell upon the floor, and her extreme weakness having prevented her from getting up, she remained in that state until some one entered, and put her to bed. The following night she wished to be left alone. A woman quitted her at half-past eleven, and, according to custom, shut the door and locked it. She had put on the fire two large pieces of coal, and placed a light in a candlestick on a chair at the head of her bed. At half-past five in the morning, a smoke was seen issuing through the window, and the door being broke open, some flames which were in the room were soon extinguished. Between the bed and the chimney were found the remains of the unfortunate Clues. One leg and a thigh were still entire,

but there remained nothing of the skin, the muscles, or the viscera; the bones of the cranium, the breast, the spine, and the upper extremities were entirely calcined, and covered with a whitish efflorescence. The furniture had sustained but little injury. The side of the bed which was next the chimney had suffered most; the wood of it was slightly burnt, but the feather bed, the clothes, and covering, were safe. I entered the apartment about two hours after it had been opened, and observed that the walls and every thing in it were blackened, and that it was filled with a disagreeable vapour, but that nothing except the body exhibited any strong traces of fire."

An instance similar to this is related by Vicq. d'Azyr, in the *Encyclopædie Methodique*. A woman about fifty years of age, who indulged to excess in spirituous liquors, and got drunk every day before she went to bed, was found entirely burnt and reduced to ashes. Some of the osseous parts only were left, but the furniture of the room had sustained very little damage. The same author adds, that there have been many other instances of the same kind. We find also a circumstance of this kind in a work entitled *Acta Medica et Philosophica Hafniensia*, and in the work of Henry Bohenser, entitled *Le Nouveau Phosphore Enflammé*. A woman at Paris who had been accustomed for three years to drink spirits of wine to such a degree that she used no other liquor, was one day found entirely reduced to ashes, except the skull and extremities of her fingers.

The *Philosophical Transactions* contain an instance of human combustion no less extraordinary. Grace Pitt, the wife of a fishmonger in the parish of St. Clement, Ipswich, aged about sixty, had contracted a habit, which she continued for several years, of coming down every night from her bed-room, half dressed, to smoke a pipe. On the night of the 9th of April, she got up as usual: her daughter, who slept with her, did not perceive she was absent till next morning when she awoke. Soon after which she put on her clothes, and going down to the kitchen, found her mother stretched on the right side, with her head near the grate, her body extended on the hearth, with her legs on the floor, which was of deal, having the appearance of a log of wood consumed by fire without any apparent flame. On beholding this spectacle, the girl ran in great haste, and poured over her mother's body some water contained in two large vessels, in order to extinguish the fire; while the fetid odour and smoke which exhaled from the body almost suffocated the neighbours who ran to the girl's assistance. The trunk was in some measure incinerated, and resembled a heap of coals covered over with white ashes. The head, the legs, the arms, and the thighs had also participated in the burning. The woman, it is said, had drank a large quantity of spirituous liquor for joy, on learning that one of her daughters had returned from Gibraltar. There was no fire in the grate, and the candle was found entirely burnt out in the socket of the candlestick, which was close by her. Besides which, there were found near the consumed body, the clothes of a child and a paper screen, which had sustained no injury by the fire. The dress of this woman consisted of a cotton gown.

Le Cat, in a memoir on spontaneous burning, mentions several other instances of combustion of the human body. He lodged at Rheims, in 1725, at the house of Sieur Millet, whose wife was intoxicated every day. "The domestic economy of the family," he observes, "was managed by a pretty young girl, which I must not forget to remark, in order that all the circumstances which I am about to relate may be properly understood. This woman was found consumed on the 20th of February, 1725, at the distance of a foot and a half from the hearth in the kitchen. A part of the head only, with a portion of the lower extremities, and a few of the vertebræ had escaped combustion. A foot and a half of the flooring under the body had been consumed, but a kneading trough and a powdering tub, which were very near the body, had sustained no injury. M. Chretien, a surgeon, examined the remains of the body with every judicial formality. Jean Millet, the husband, being interrogated by the judges who instituted an inquiry into the affair, declared that about eight in the evening of the 19th of February, he had retired to rest with his wife, who not being able to sleep, had gone into the kitchen, for the purpose, he thought, of warming herself; that having fallen asleep, he was awakened about two o'clock by an infectious odour, and that having run into the kitchen, he found the remains of his wife in the state described by the physicians and surgeons. The judges having no suspicion of the real cause of the affair, prosecuted the inquiry with the utmost diligence. It was very unfortunate for Millet, that he had a *beautiful* maid servant, for neither his probity nor innocence was able to save him from the suspicion of having got rid of his wife by a concerted plot; and of having arranged the arts of the circumstance in such a manner as to give it the appearance of an accident. He experienced therefore the whole severity of the law; and although by an appeal to a superior and enlightened court, which discovered the cause of the combustion, he came off victorious, he suffered so much from uneasiness of mind, that he was obliged to pass the remainder of his melancholy days in a hospital.

The *Journal de Medicine*, vol. 59, p. 440, contains an account of a similar case related by M. Muraire, a surgeon, as occurring at the town of Aix, in Provence. "In the month of Feb. 1779, Mary Jauffret, widow of Nicholas Gravier, shoemaker, of a small size, exceedingly corpulent and addicted to drinking, having been burnt in her apartment; M. Rocas, my colleague, who was commissioned to make a report on the state of her body, found only a mass of ashes and a few bones, calcined in such a manner, that at the least pressure they crumbled into dust. The bones of the cranium, one hand, and a foot, had in some measure resisted the action of the fire. Near these remains stood a table untouched, and under the table a small stove, the grating of which having been long burnt, afforded an aperture, through which it is probable the fire, which occasioned the melancholy accident, had been communicated: one chair which stood near the flames had the seat and fore-feet burnt. In other respects there was no appearance of fire either in the chimney or the apartment; so that, except the fore-part of the chair, it appears to me, that no other combustible matter contributed to this speedy incineration, which was effected in the space of seven or eight hours."

Another case contained in the *Journal de Medicine* occurred at Caen, and is thus related by M. Merille, a surgeon of that place. Being requested on the 3d of June, 1782, by the king's officers to draw up a report of the state in which I found Mdlle. de Thuars,

who was said to have been burnt, I made the following observations:—The body lay with the crown of the head resting on one of the irons, at the distance of eighteen inches from the fire; the remainder of the body was placed obliquely before the chimney, the whole being nothing but a mass of ashes. Even the most solid bones had lost their form and consistence; none of them could be distinguished except the coronal, the two parietal bones, the two lumber vertebræ, and a portion of the tibia; and these even were so calcined, that they became dust by the least pressure. The right foot was found entire, and scorched at its upper junction; the left was more burnt. The day had been cold, but there was nothing in the grate except a few pieces of wood, about an inch in diameter, burnt in the middle; none of the furniture in the apartment was damaged. The chair on which Mdlle. Thuars had been sitting was found at the distance of a foot from her, and absolutely untouched. This lady was exceedingly corpulent; she was about 60 years of age, and much addicted to spirituous liquors; the day of her death she had drank about three bottles of wine and *one bottle* of brandy, and the consumption of her body had taken place in less than seven hours."

The case which we shall now relate was attended with circumstances of peculiar interest, because the unhappy man survived the accident some time, and gave an account of the various circumstances by which it was preceded and followed. The case was published in one of the journals of Florence, for October, 1776, by M. Battgalia, the surgeon who attended the unfortunate sufferer. Gio. Maria Bertholi, resident priest at Monte Volere, went on business to a neighbouring fair; and having spent the day in walking about the country, arrived in the evening at Jernielle, intending to sleep at the house of his brother-in-law. He was immediately on his arrival, at his own request, conducted to his chamber, when he had a handkerchief placed between his shirt and shoulders, and immediately commenced his devotions. But a few minutes had elapsed, when an uncommon noise, attended with cries, was heard issuing from his apartment. The people of the house were alarmed, and rushing in, found the priest stretched out upon the floor and surrounded by a light flame, which receded as they approached, and ultimately vanished. He was immediately placed in bed, and on the following morning visited by the surgeon, who, on examination, found the skin of the right arm and fore-arm detached from the muscles, and hanging loose. From the shoulders to the thighs the integuments were similarly injured. These detached portions of skin having been altogether removed, and mortification being perceived on the right hand, which had suffered most severely, the parts were scarified. Notwithstanding this precaution, it had fallen the next day into a state of gangrene. On the third day, all the other scorched parts were discovered to have degenerated into the same condition. The unhappy man complained of unquenchable thirst, and was horridly convulsed; the discharges from his mouth were putrid and bilious, and his strength was exhausted by continual vomitings, accompanied with delirium and a burning fever. After lying two hours in a state of insensibility, he expired on the fourth day. While he lay in this lethargic sleep, his attendant observed with astonishment that putrefaction had made considerable progress, so that the body exhaled an intolerable odour, and the nails were spontaneously detached from the fingers of the left hand. This unfortunate man informed the surgeon, that first of all he had felt a blow, like that inflicted by a cudgel, upon the right arm; and that at the same time he saw a light blue flame attach itself to his shirt, which was instantly reduced to ashes, yet his wristbands at the same time remained untouched. The handkerchief across his shoulders remained untouched. The lower part of his dress had escaped, but his cap was entirely consumed, although not a hair of his head had suffered by the flame. All the symptoms of the disease were those of a severe burn. The night of the accident was calm, and the atmosphere very clear; no empyreumatic smell, nor appearance of smoke was perceived in the chamber; but the lamp, before full of oil, was become dry, and its wick reduced to a cinder.

St. Hurmius, in the *German Ephemerides*, says, that in the northern countries, flames often burst from the stomachs of persons in a state of intoxication.—Three noblemen of Courland having laid a bet which of them would drink the most spirits, two of them died in consequence of suffocation by the flames, which issued in great violence from their stomachs.

On the night of the 16th of March, 1802, in one of the towns of the State of Massachussetts, the body of an elderly woman disappeared from some internal cause, in the duration of about one hour and a half. Part of the family had gone to bed, and the rest were abroad. Shortly after, one of the grandchildren came home, and discovered the floor near the hearth to be on fire. An alarm was made; a light brought—and means used to extinguish it.—While these things were being done, some singular circumstances were observed on the hearth and the contiguous floor. There was a sort of greasy soot and ashes, with remains of a human body, and an unusual smell about the room. All the clothes were consumed, and the grandmother was missing. It was at first supposed she had, in attempting to light her pipe, fallen into the fire and been burned to death; but every thing confirmed the idea of spontaneous combustion.

The spontaneous combustion of *vegetable substances* is a matter of no less interest to the judicious inquirer, than that of animal bodies. This too is peculiar, because it is a deviation from the ordinary course of nature, and there can be no doubt but it often occurs, giving rise to many of those conflagrations for the origin of which no adequate cause can be assigned, but where a suspicion of other causes is very often implicated. When spontaneous combustion occurs in vegetable substance, in every instance either phosphorus or one of its combinations, or a vegetable essential oil, with some light fibrous matter is present. Chemists have, however, but barely noticed the subject. Dr. Henry states, that the expressed oils possess the remarkable property of inflaming any light vegetable matter or carbon with which they may come in contact. Hay, charcoal, dunghills, and pigeons' dung, with many other substances, have long been reputed to be liable to spontaneous combustion.

Perhaps the most remarkable cases of spontaneous combustion, are those in which it has arisen in clothes, saturated probably with a peculiar animal matter emitted in perspiration. John de Viano, in a treatise *De Peste Malagensis*, p. 46, relates, that the wife of

Dr. Freilas, physician to the Cardinal de Royas, Archbishop of Toledo, sent forth naturally by perspiration, a fiery matter, that if the roller that she had worn round her body was taken from her and exposed to the atmosphere, it was immediately kindled, and shot forth like grains of gunpowder. And Peter Borelli says, "there was a certain peasant, whose linen, hempen thread, &c., if laid up in boxes, though wet through, or hung upon sticks in the air, did soon take fire."

Charcoal has frequently been known to ignite spontaneously. Two instances of this kind of combustion took place in the powder-manufactory of Essones, in the years 1708 and 1709. The first time, the fire broke out in the box employed for sifting the charcoal; and the second time, the charcoal repository took fire: on each occasion there were no data to which to ascribe the accidents, but to spontaneous inflammation. The reports of these two events, with the opinions of the French philosophers, were inserted in the public journals of the day. Three successive explosions likewise took place in the mills of Vonges; these were attributed to the same cause.—It appears very probable that in these cases, the immediate cause of the combustion is the phosphorus contained in charcoal; this explanation is the more founded on reason, because the alder wood used at Essones, as well as in most continental gunpowder manufactories (and on which account it maintains a preference over other woods for making gunpowder), contains much phosphoric acid.

Instances have been known in which houses have been set on fire, by ashes intermingled with charcoal, being taken too hot from the hearth, and which having been deposited in places where they were surrounded with combustibles, have occasioned inflammation. Happily this cause of fire rarely occurs; but care should be taken not to put ashes which are newly burnt, and which are still mixed with charcoal, in places where they may have a communication with combustibles.

There are many vegetable substances, which by torrefaction acquire an increase of property to ignite spontaneously, particularly in situations where they are exposed to the action of the atmosphere. Of this kind are saw-dust, burnt coffee, the farina of gramineous, and the fruits of leguminous plants, such as beans, peas, lentils, &c.

The following singular case of spontaneous combustion is described by Mr. James Gullonan, of Glasgow, in the seventh volume of the *Edinburgh Philosophical Journal.* "Having sold a respectable dealer a parcel of sample bottles, I sent them to him in an old basket, the bottom of which was much broken.—To prevent the bottles from falling through, I put across the bottom of the basket a piece of old packing sheet, which had lain long about an oil and colour warehouse, and was besmeared with different kinds of vegetable oil. About six or eight weeks after, the gentleman informed me, that my oily cloth and basket had almost set his warehouse on fire. The basket and cloth had been thrown behind some spirit casks pretty much confined from the air, and about mid-day he was alarmed with the smell of fire.—Having moved away the cases in the direction where the smoke issued, he saw the basket and cloth in a blaze.

The eighty-fourth volume of the *Philosophical Transactions* contains the following case, which happened at Bombay. On going into the arsenal (observes the writer, Isaac Humphries, Esq.), I found my friend Mr. Goulding, the commissary of stores, in the greatest uneasiness in consequence of an accident which had happened the preceding night. A bottle of linseed oil had been left on a table, close to which stood a chest containing some coarse cotton cloth. In the course of the night the bottle of oil had been thrown down and broken on the chest (by rats most probably), and part of the oil ran into the chest, and on the cloth; when the chest was opened in the morning, the cloth was found in a very strong degree of heat. and partly reduced to tinder, and the wood of the box was also discoloured, as by burning. After a most minute examination, no appearance of any other inflammable substance could be found, and how the cloth could have been reduced to the condition in which it was found, no one could conjecture. The idea which occurred to, and made Mr. Goulding so uneasy was, that of an attempt to burn the arsenal. Thus matters were when I joined him, and when he told me the story, and showed me the remainder of the cloth. It luckily happened that, in the course of some chemical amusements, I had occasion to consult *Hopson's Chemistry* a few days before, and there I met with a particular passage on spontaneous combustion, which fully explained the fact to which my friend had adverted.

One of the most singular well-accredited cases of spontaneous combustion that we recollect to have seen, is described in the *American Journal of Science* for 1832. The author thus describes the phenomenon:—"We have, in our family room, adjoining the kitchen, a Philadelphia cooking-stove, in which, when the weather is cold and the price of fuel is high, some little culinary processes are at times carried on. For this winter the floor has been covered with some cheap domestic carpeting. The stove stands on the carpet, which being tacked down, and covered in places with oil-cloths, has not been taken up during the winter. Of course, some grease spots had appeared contiguous to a side door of the stove, but they had been scoured off so as hardly to be discernable on the upper surface.

"Some weeks ago, about noon, I was writing in this apartment, and having in charge two little children, the oldest one then called my attention to the smoke which then filled the room. My first impression was, that the house was on fire, probably in the kitchen; but on opening the door, first of that room, and then of the parlour, no smoke was perceived in either, and I closed those doors, and began to search more narrowly. On looking at the carpet, I could see the smoke rising through it everywhere. I then looked into the cellar, found no smoke there, and closed the door, to prevent too free an ingress of air, and the bursting into flame. The carpet was then carefully examined by the eye and hand, and one spot was found, and only one, where there was heat enough to make smoke. That spot was on one side of the stove, more than two feet distant from it, and the carpet was whole, though warmed, but not hot, for I could bear my hand upon it. I applied some snow to it, and found a browned spot of about two inches in diameter, which soon became a hole of that size, corresponding with one in the white pine floor-plank underneath, which was browned and charred, not burned, less than half-way through the plank. This occurred in a seam of the floor, where the

planks were joined, and in what had been one of the spots of grease: whether in contact with a nail, I have not yet ascertained. This is clearly an alarming case of *incipient spontaneous combustion.* The carpet, the materials of which had, till now, escaped observation, was found to be made of cotton and flax tow, with streaks of woollen yarn filling, none of which, however, came within the charred hole above described. In the hope to guard others against similar dangers, these facts are communicated."

We stated at the outset of this article that we had little more than *facts* to communicate. In the present state of our knowledge on the subject, it would be improper to theorise. There is, however, one important lesson to be derived from a perusal of these accredited cases of spontaneous combustion,—namely, to weigh well the evidence which is adduced in cases of incendiarism, and pause ere we condemn an accused person to an ignominious death, when the mischief of which the individual is accused may have originated in accidental circumstances.

COME SOPRA, in *music*, an allusion to the manner of performing some former passage, the style of which performance has been already denoted.

COME STA, in *music*, an expression implying that the performer is not to embellish the passage with any additions of his own.

COMETS. See ASTRONOMY and ECLIPSE.

COMMENSURABLE; among geometricians, an appellation given to such quantites or magnitudes as can be measured by one and the same common measure.

Commensurable numbers, whether integers or fractions, are such as can be measured or divided by some other number, without any remainder: such are 12 and 18, as being measured by 6 or 3.

COMMERCE OF THE WORLD. This embraces the whole subject of the traffic and intercourse of nations, and shows how mutual wants, occasioning the exchange of natural riches for the creations of art, unite savage nations with civilized, and spreads moral and social cultivation over the earth. In former times, commerce subdued the *steppes* of Scythia and the deserts of Libya, and it is now clearing away the primitive forests of America, and draining the waters of Australia. For thousands of years, it has pervaded the interior of the ancient world; for centuries it has had its path on the mighty ocean; and of late it has studied how to cut through the isthmus of Darien, and to break through the ice of the poles. In the history of nations, it is a perpetual Argonautic expedition, and, from the first period of commerce down to our own times, its Colchis has been India. The limits of our work do not allow us to exhibit the progress of commerce in ancient times, and we shall merely give a cursory survey of the principal commercial nations of the present period.

I. EUROPE, since the conquest of Tyre by Alexander, has been in the possession of the commerce of the world, and has secured it by its colonial system, by means of which it exercises the monopoly of colonial commodities. By this we understand the productions of the planting, commercial, and mining colonies; those of the last, however, only in part, for the precious metals and stones can hardly be designated by that name. This is also true of the productions of the colonies more strictly agricultural: spices, East India goods of all kinds, dye-woods and cabinet-woods, drugs, cotton, and especially coffee, sugar, rice, tea, &c., are properly understood by this term. The East Indies furnish chiefly cotton, sugar, coffee, rice, fabrics of various kinds, spices, and tea (from China); the West Indies, cocoa, coffee, sugar, and cotton; South America, the precious stones and metals, dye-woods, cabinet-woods, drugs, &c. The consumption of these articles, which was formerly possible only for the rich, has increased immensely since the ocean became the highway for trade with the East Indies and America, in the course of the 15th century, and more especially since the English and Dutch assumed the first station among the colonial nations of Europe, in the beginning of the 18th century. Instead of being, as before, mere objects of luxury for the higher ranks, colonial goods became necessary articles even for the lowest classes of Europe; and an entire revolution was produced in the civil and political condition of that portion of the world. Commerce thus acquired an incomparably higher importance, and a more general interest. The class of merchants, which was by this means increased in an extraordinary degree, soon formed a body of men, spread over the whole cultivated world, and animated by one purpose—to maintain commerce; and even among belligerent nations, governments have endeavoured in vain utterly to abolish the mutual dealings of merchants. Thus, as the intercourse of nations became more lively, the exchange of ideas was promoted, men's views became enlarged, a cosmopolitan spirit united distant communities, and formed of the nations of Europe, as it were, one great, civilized family. Equal results were produced by the increased importance of the colonial powers (in late times, the two maritime states of England and Holland, in particular), arising from the increasing consumption of colonial goods. For them, and, indeed, though in an inferior degree, for the other colonial powers of Europe, the trade in the productions of the colonies was an important source of wealth and power. Their great political importance has exercised an extensive influence on the whole political condition of Europe. England in particular, has become continually more powerful by its extensive trade. It was therefore in the natural course of things, that, when the immense power of France was developed by the revolution, and that country, under Napoleon, strove for predominance on the European continent, the greatest struggle should take place between France and England, a consequence of which was the continental system of Napoleon, who declared his purposes to be, to free Europe from the tribute which it was obliged to pay to England for the colonial goods which it received from her. England, deeming it absolutely essential to her interests to prevent the establishment of an universal monarchy on the continent, spared no exertion to procure the restoration of the former order of things, so that she might have a free intercourse with the continental ports. Without going into the points at issue between Great Britain and France, the fact deserves to be stated, that the continental system called into action many kinds of industry on the continent, and, in this way, has produced important changes in the course of trade, resulting from the great increase of manufactures. If we examine whether it be actually true, as asserted in the time of the continental system, that the great use of colonial goods must necessarily produce poverty, it is easy to prove the contrary, which has been already fully con-

formed by experience. New wants gave rise to new energy and new branches of industry, in order to gratify those wants, thus increasing the productiveness of labour, and, simultaneously, the prosperity of every nation. But it is objected that money, or the produce of labour, which would otherwise remain in the various countries, is sent away from them in exchange for colonial goods. Very true; but, even if the express purpose of acquisition were not to procure new enjoyments, the object of all trade and all activity is, not to accumulate money, but to augment the sum of happiness. If this object be attained, industry and trade have effected all that they should do. Of course, no account can be reasonably taken of the small number of idle spendthrifts, who, without labouring, consume their capital in gratifying their pleasures. But it was soon perceived, that, in the existing state of Europe, entirely to exclude colonial articles was utterly impossible, though recourse was had to all kinds of substitutes. The enormous duties imposed on the importation of colonial goods, as far as the French power then reached, that is, throughout nearly all the continent of Europe, contributed essentially to render its nations poorer; for these duties had to be paid, while nothing of value could be given in return, from which circumstance originated a most pernicious and immoral smuggling trade. But Napoleon asserted that the English would not allow him to make peace, in which case the whole system would naturally have been changed.

In the 18th century, *Great Britain* became the first colonial power. It, therefore, stands at the head of the commercial nations, who are all, more or less, tributary to British art and industry. Its commerce is, in a great measure, managed by companies.

The chief exports of Great Britain are, to the north of Europe, cotton and woollen cloth, glass, hardware, pottery, lead, tin, coal, East India and colonial wares, dye-stuffs, salt, and refined sugar. In return, Great Britain receives from the north, corn, flax, hemp, iron, turpentine, tar, tallow, timber, linen, pearl and pot-ashes, cordage and hog's bristles. To Germany, Holland, France, Italy, Spain, and Portugal, it exports cotton and woollen fabrics, cutlery, dried and salt fish, pottery and glass-ware, colonial and East India goods, and all kinds of the finer manufactures. From Germany it imports corn, flax, hemp, linen cloth and thread, rags, hides, timber, and wine. From Holland, flax, hemp, madder, gin, cheese, butter, rags, and seeds. From France, wine, brandy, lace, cambric, silk ornaments, and fancy goods and fruit. From Italy, Spain, and Portugal, silk, wool, barilla, sulphur, salt, oil, fruit, wine, brandy, and cork. To Turkey it sends cotton and woollen goods, hardware, colonial and East India goods, lead, tin, iron, clocks, and watches; receiving, in return, coffee, silk, fruits, fine oil, dye-stuffs, carpets, &c. To North America it sends woollen and cotton manufactures, hardware, linen, glass, and other wares: the imports from thence are flour, cotton, rice, tar, pitch, pot and pearl-ashes, provisions, ship-timber, &c. The chief imports from South America are cotton, hides, skins, tallow, cochineal, dye-wood, sugar, indigo, cocoa, gums, &c.; and the exports from England are the same as above mentioned. The same exports are likewise sent to the West Indies; and, in return, Great Britain receives rum, coffee, tobacco, sugar, ginger, pimento, pepper, indigo, dye-stuffs, drugs, gums, cotton, mahogany, Campeachy wood, &c. To the East Indies, China, and Persia, it sends woollen goods, iron, copper, lead, tin, foreign silver money, gold and silver in bars, hardware, and a variety of manufactures; for which it obtains muslins, calicoes, silks, nankeens, tea, spices, arack, sugar, coffee, rice, saltpetre, indigo, opium, drugs, gums, quicksilver, precious stones, pearls, &c. To the colony of New South Wales, the common English manufactures and colonial goods are exported, and exchanged for train-oil, seal-skins, wool, &c.

Internally, Great Britain trades in the following commodities. From Scotland, England and Ireland receive corn, cattle, woollen and cotton goods, pot-ash, coals, canvass, and iron manufactures; the Scottish fisheries also furnish an important article of commerce. For these things, Scotland receives the productions of Ireland, and articles of luxury, of all kinds, from England. Ireland buys of England and Scotland, woollen, cotton and silk goods, East and West India goods, pottery, hardware, and salt; and, in exchange, gives its linen, hides, potatoes, and other provisions, &c. The foreign commerce of Ireland is, besides, very extensive. It exports its productions and manufactures to France, Spain, Portugal, the West Indies, and North America, for wine, fruit, sugar, rum, &c. The commercial intercourse between Ireland and the north of Europe is mainly through England, and its trade with the East passes exclusively through the same channel. The chief articles of export from Ireland are linen, potatoes and other provisions, corn, whiskey, herrings, and salmon.

The foreign possessions, settlements, and colonies of Great Britain, of which it possessed 26 prior to the French revolution, and has gained 17 more by conquest, are Heligoland, Gibraltar, and Malta, with Gozo and the Ionian Isles, in Europe; its possessions in India, under the administration of the East India Company, and Ceylon, in Asia; the Isle de France, or Mauritius, with the Sechelles and Amirante Isles, the Cape of Good Hope, Sierra Leone, Cape Coast and Annaboa, the islands of Ascension and St. Helena, in Africa; Canada, New Brunswick, Nova Scotia, Cape Breton, St. John's, or Prince Edward's Island, Newfoundland, Hudson's Bay, and the bay of Honduras, in North America; Berbice, Essequibo, and Demerara, in South America; Jamaica, Barbadoes, Antigua, St. Vincent, St. Christopher, Nevis, Montserrat, the Virgin Islands, Grenada, Tobago, Dominica, Trinidad, and the Bahamas, in the West Indies; also the Bermudas; in Australia, New South Wales, Van Diemen's Land, and the colony of New Zealand, and Melville's Island.

The most important commercial cities of England, besides London, are Liverpool, Bristol, and Hull; the most important manufacturing towns are, Manchester, Birmingham, Leeds, Nottingham, Halifax, Rochdale, &c. In Scotland, the principal commercial places are Glasgow, Greenock, Leith, and Aberdeen. The foreign trade of Glasgow and Greenock extends to the West Indies, the United States, the British American colonies, Brazil, and the whole continent of Europe. The foreign trade of Leith and Aberdeen extends to the West Indies, America, the Mediterranean, and the Baltic. The greatest commercial cities of Ireland are, Dublin, Cork, Wexford, Waterford, and Belfast.

TABLE I.

An Account of the Official and Declared Value of the Imports to and Exports from the United Kingdom, from and to each of the British Colonies and Possessions, for the Year ending 5th January, 1831; *being the last account laid before the House of Commons; distinguishing British and Colonial and Foreign Produce.*

Names of the British Colonies, &c.	Official Value of Imports into the United Kingdom.			Official Value of Exports from the United Kingdom.						Declared Value of British and Irish Produce and Manufactures exported from the United Kingdom.

The preceding tables exhibit a view of the gross amount of the commerce of this country, distinguishing the component portions of it carried on with each colony and foreign states for the year ending 5th January, 1831. The like accounts for the following year have not yet been printed by the House of Commons; we are enabled, therefore, to give only the gross amount of the commerce of the United Kingdom with foreign countries during that period.

Trade of Great Britain with Foreign Parts for the Year ending 5th January, 1832.

Exports:	Official value.	Real value.
British and Irish produce and manufactures . .	£. 60,090,123	£. 36,652,694
Colonial and foreign produce	10,729,943	—
Imports	48,161,661	—

Trade of Ireland with Foreign Parts for the Year ending 5th January, 1832.

Exports:	Official value.	Real value.
British and Irish produce and manufactures . .	£. 593,810	£. 510,953
Colonial and foreign produce	15,129	—
Imports	1,552,228	—

Germany. On account of its navigable rivers, the commerce of this country is considerable. The chief articles of export are linen, linen yarn, raw wool, rags, quicksilver, corn, timber, flax, hemp, wax, lard, salt, wine, and metals. Its imports are woollens, cottons and silks, hardware, watches, tanned leather, leather goods, tea, cocoa, dye-woods, hides, colonial and East India goods. The principal ports of Germany are Hamburg, Lubeck, Bremen, Trieste, and Dantzic. In the interior its chief commercial cities are Vienna, Magdeburg, Leipsic, Frankfort on the Maine, Frankfort on the Oder, Augsburg, Berlin, Breslau, Cologne, Nuremberg, Brunswick, Mentz, Botzen, and Prague. Hamburg, in particular, is the channel through which flows, for the most part, the extensive trade between Great Britain and the German states. By means of the rivers running into the Elbe, the navigation of which has now become free, the numerous and valuable productions of Upper and Lower Saxony, of Austria, and Bohemia, go to Hamburg. By the Havel, the Spree, and the Oder, its commercial operations are extended to Brandenburg, Silesia, Moravia, and Poland. The business of Hamburg consists, in part, of the consignments of foreign merchants, and, to a great extent, of the purchase and sale of domestic and foreign goods. Its money transactions are very considerable. Bremen has important articles of export in the products of Westphalia and Lower Saxony, which it sends to England, Spain, and Portugal; and with America it has more intercourse than any other seaport of Germany. The trade in linens, which foreign countries carry on with Germany, passes wholly through the hands of the Hamburg and Bremen merchants, to whom all foreign orders are directed. The importation of tobacco from America into Germany is almost wholly through Bremen. Leipsic, the centre of European trade with the interior of Germany, and the place of deposit for foreign and Saxon goods, has, besides other mercantile privileges, three fairs (Easter, Michaelmas, and the New Year), to which merchants resort from all parts of Europe, and from Asia, and each of which lasts three weeks: there is, besides, at this place, a considerable market for Saxon wool. The chief articles of traffic are Bohemian, Silesian, and Saxon linen; leather, hides, wax, and wool, from Poland; woollen goods and pigments, from Prussia; silks, velvets, and corals from Italy; leather, various manufactures, and dye-stuffs, from Austria and Hungary; laces, silk goods of all kinds, ribbons, porcelain, watches, bronze and other manufactures, including fancy articles, from France; leather, hemp, and flax, from Russia; colonial commodities and manufactures, from England and Holland; and literary productions from all Europe. There is, also, in Leipsic, an important horse-market. Augsburg, by means of its agents and bankers, is the medium of mercantile communication between Germany and the south of Europe. The exchange business of Vienna is commonly transacted by drafts on Augsburg. It also derives considerable advantage from the forwarding of goods to and from Italy. Frankfort on the Maine, a place of great commercial activity, especially at the time of its two great fairs, in the spring and autumn, has, besides, a very important business, owing to the opulence of its old and new banking-houses. It is the commercial centre for the Rothschilds. In Brunswick, considerable business is transacted in its natural productions and manufactured articles, as well as in foreign goods. Its two great yearly fairs rank immediately after those of Leipsic and Frankfort. Great quantities of raw thread are sent thither by the Dutch merchants, and the strong beer, called *mum*, is exported to various parts of the world.

Austria is entirely separated from Germany by its system of imposts and its commercial regulations. Its trade is mostly carried on by land, or on the rivers. Vienna, the store-house of the inland trade of all Austria, has a very extensive commerce with England, the Netherlands, and France, and important dealings with Italy, Hungary, Poland, and Turkey. By the way of Vienna, Germany receives great quantities of raw cotton from Turkey. The commerce of Trieste, in the Littorale, consists chiefly in the exportation of German productions and of colonial goods, which go from thence to the Levant and the coasts of the Black Sea. Trieste may be regarded as the depôt of the productions of the Levant. It is also actively engaged in the importation of British wares, and of the produce of the fisheries of Newfoundland. Except this city, the commerce of Austria is confined to Venice and Fiume. The most considerable places of inland trade in the monarchy, besides Vienna, are Lemberg, Prague, Brunn, Brody, Botzen, Pest, and Cronstadt. The allowed imports consist mainly of raw produce, cotton and wool, silk, rice, oil, spices, colonial articles, leather, cattle, &c. The articles of export are woollen cloths, linens, cordage, mineral productions, grain, and glass. Great profit is derived from the transportation of goods, especially of those of the Levant. In Bohemia, far the greater portion of the trade is in the hands of the Jews, who are numerous in the country. The trade is chiefly in exports: linens, woollens, silks, dye-wood, leather, and glass. The glass is superior in polish and cheapness to that of other countries, and the exportation of it is very considerable. It is thought that the goods exported to Spain, Russia, the Levant, and America, amount to 2,500,000 guilders annually. The countries with which Bo-

hemia has the most commercial intercourse are Austria, Holland, Spain, Portugal, Italy, and Turkey. The exports are rated at from 5,000,000 to 6,000,000 dollars, and the imports (colonial goods, articles of luxury, &c.) at from 4,000,000 to 5,000,000 dollars. Prague is the first commercial city of the country; Reichenberg the second.

Prussia has likewise, by its system of prohibition, been separated from Germany with respect to free commercial intercourse, especially since 1818. The commerce of this monarchy is promoted by the Baltic, by many navigable rivers, and by canals. The commerce in domestic productions is more important than the transportation and commission trade, which flourishes mainly in Cologne, Magdeburg, Stettin, Minden, Dantzic, Königsberg, Breslau, &c. The exports by sea are grain, wax, tallow, wool, linseed, flax, hemp, wood, linen, yarn, woollen and cotton goods, fine works of art, including articles made of amber. Of the different commercial places, Frankfort on the Oder has three considerable fairs. Magdeburg sends corn, linen, cotton goods, cloths, leather, salt, and copper, to Hamburg, and to the fairs of Leipsic and Brunswick. It has, besides, a transit trade in colonial goods, wine, grain, &c. Wheat is exported from Dantzic, which possesses the largest granary in Europe; from Elbingen, Stettin, Königsberg, Anclam, and Berlin, timber; staves and ashes from Dantzic, Memel, and Stettin; hemp, flax and linseed, tallow, wax, and hog's bristles from Memel and Königsberg. Tilsit carries on a brisk trade in corn, linseed, hemp, and flax. The exports of Brunsberg are woollen yarn, corn, and flax. Colberg exports corn, and the other produce of Poland. The trade of Stralsund, likewise, consists chiefly in the exportation of corn. Of all the articles of Prussian commerce, the Silesian linen holds the first rank, and for the manufacturing of it, the Silesian towns Hirschberg, Landshut, Schmiedeberg, Friedland, Waldenburg, Schweidnitz, and the Prussian section of Upper Lusatia, are celebrated. This linen is particularly in demand among the Hamburg, English, Dutch, Italian, and South American merchants. The imports which have the readiest sale in Prussia are colonial goods, dye-wood, salt, Buenos Ayres hides, indigo, groceries, wine, silk, cotton goods, hardware, &c.

Hanover is not distinguished for its mercantile activity. The exports consist of horses, horned cattle, lead, wax, linen, leather, salt, oats, barley, timber, boards, and the ferruginous copper of the Hartz mountains. The linens are ordinary; the tablecloths and Osnabruck damask are inferior in quality to those of Prussia and Friesland. The surplus of the domestic consumption is exported to South America through the medium of the Hanseatic cities. The principal imports are English manufactures, especially woollen cloths and calicoes, colonial goods, Prussian and Friesland linen, fine French cloths, silks, jewellery, and French wines, with all kinds of small articles of luxury, which the Hanoverian merchant brings with him from the fairs of Brunswick, Leipsic, and Frankfort on the Maine. The chief commercial towns are Emden, Hanover, and Münden.

Denmark and Holstein. Although the Danish merchants have formed connections with all the commercial states of Europe, and play an important part in the commerce both of the Mediterranean and the Baltic, their own country possesses but few productions important as articles of export. Most of what they export are the productions of their East and West India possessions. To the ports of Petersburg, Riga, Stockholm, and Memel, Denmark carries the woollen goods of Iceland and the Faroe Islands; salt from Spain, France, and Portugal; and the productions of the East and West Indies and of China. To Germany it sends its horses, its cattle, colonial and West India goods, and woollen stockings, receiving in return linen, wool, brandy, and wine. To Holland it exports rape-seed, fish, &c., in exchange for groceries. To France, Spain, and Portugal it carries horses, fish, and other articles from Russia, in exchange for salt, wine, fruits, sweet-oil, brandy, silk, &c. Its trade with England consists, mainly, in exchanging timber, &c. for English manufactures. To Iceland it exports rye-meal, rye, barley, brandy, and other spirituous liquors, together with the common articles of consumption; receiving in return fresh, dry, and salt fish, train-oil, tallow, eider down, wool and woollen stockings. It supplies Greenland with flour, spirituous liquors, &c., in return for train and seal oil, seal-skins, eider down, and peltry.

The largest commercial towns of Denmark are Copenhagen and Elsinore in Zealand, Aalborg in Jutland, Flensborg and Tonningen in Sleswic, Altona and Kiel in Holstein. The West India colonies of Denmark are St. Croix, St. Thomas, and St. John's. On the coast of Coromandel, it possesses Tranquebar; on the coast of Guinea, Christianborg and other small places. It has also small factories on the Nicobar islands. In Europe it possesses Iceland. The chief commercial companies in Denmark are, the Asiatic or East India Company, the Iceland Company, the Maritime Insurance Company, the African or Danish West India, and the General Commercial Society.

France. The commerce of France extends to every country of the world. The exports are wine, brandy, oil, corn, meal, liqueurs, snuff, silks, woollens, fancy goods of all kinds, watches, porcelain, crystals, carpets, bronze, linen, lace, cambric, tapestry, hemp, flax, fruits, capers, salt, jewellery, paper, &c.; and France receives the raw produce of all countries, but very few manufactured goods. In 1824, the value of all the exports of France was 440,542,000 francs, of which 163,056,000 were in natural products, and 277,486,000 in manufactured goods. In the same year goods were imported into France to the amount of 189,535,000 francs in 3,387 French vessels, to the amount of 108,397,000 francs in 4,183 foreign vessels, and to the amount of 156,929,000 by land; the whole importation amounted to 454,861,000 francs. The principal ports are Bordeaux, Marseilles, Nantes, Havre de Grace, St. Malo, L'Orient, and Dunkirk. The commerce of Marseilles is mostly with the Levant and the West Indies; that of Bordeaux with Asia, the West Indies, and the north of Europe. Calais and Dunkirk carry on a very lucrative contraband trade with England. Havre de Grace is the seaport of Paris, which has a very extensive indirect trade, and dealings in bills of exchange with foreign countries. Amiens exports great quantities of velvet; Abbeville, Elbeuf, Louvier, and Sedan trade mainly in cloths; Cambray, Valenciennes, and Alençon, in cambrics and fine laces. Cette, the port of Montpellier, has an extensive trade in Spanish and colonial goods. The commerce of Bayonne is chiefly with

Spain. Silks form a principal article of the commerce of Lyons, which is situated in the centre of the roads leading to Switzerland, Spain, Italy, and Germany, and has annually four fairs. For Strasburg, its excellent turpentine is an important article of trade. Lisle has a direct intercourse, not only with all the commercial states of Europe, but also with the French and Spanish colonies, and with the Levant. The other commercial towns of importance are Rheims, Troyes, Grenoble, Nismes, Angouleme, Cognac, Nantes, Rouen, Rochelle, and Caen. Grenoble supplies France, Italy, Spain, and even Great Britain with fine gloves. Beaucaire has an important fair. The French colonies are Martinique, Guadaloupe, St. Lucia, and Mariegalante, in the West Indies; Cayenne, in South America, Pondicherry, Chandernagore, and some other possessions in the East Indies, with several factories on the western coast of Africa, and on both sides of Cape Verde.

Italy. Although Italy possesses the most excellent harbours on the Mediterranean and Adriatic seas, and has a geographical situation uncommonly favourable for commerce, its trade, both domestic and foreign, is very limited. The cause is to be sought in the impolitic restrictions, heavy taxes and imposts, to which the commercial cities are subjected in this most fruitful, but, for the most part, badly governed country. The chief articles of export from Italy are corn, olive-oil, wine, brandy, silk, cotton, wool, hemp, flax, velvet, damask, barilla (soda), sulphur, sumach, gall-nuts, madder, velani or velonia, and other dye-stuffs, senna leaves, liquorice juice and root, juniper berries and other drugs, anchovies, almonds, figs, nuts, olives, currants, raisins and other fruits, rags, chip and straw hats, the skins of sheep and kids, and marble. The principal commercial cities are Florence, Genoa, Leghorn, Naples, Venice, and Ancona. Leghorn is the main channel of the trade of Italy with the Levant and the Barbary states, and the central point of the commerce of England in the Mediterranean. A great part of its trade is in the hands of the Jews. Silks, taffeta, satins, brocades, light woollen goods, velvets, &c., are the main articles of export from Florence.—These pass through Leghorn, and sell readily in the Levant. Milan and Turin carry on a very extensive trade in their silk, which is celebrated throughout Europe for its admirable fineness and lightness.—Ancona has intercourse with the first commercial cities of Europe. Its business is chiefly agency and commission business. Some silk is exported from Nice. The exports of Lucca are olive-oil, silk, damasks, fruit, &c. Much olive-oil is exported from Gallipoli. The trade of Genoa continues considerable. Its exports are velvet, damask (which, next to the Venetian, is the most esteemed in Europe), raw silk, fruit, olive-oil, alum, marble, corals, coarse paper, &c. Venice, once the greatest mart of the world, notwithstanding the disappearance of its ancient splendour, is still an important place for commerce, a great part of the trade of Europe with the Levant being yet in its hands. The Venetian velvets, damasks, mirrors, and manufactured silks, in great quantities, form the most considerable constituents of the foreign trade of Venice. The exports of Naples are olive-oil, wool, silk, tartar, wines, raw and manufactured silk, fruit, sulphur, and staves.

The Islands of the Mediterranean Sea. The exports of Sicily, a country on which nature, with profuse generosity, has lavished in abundance all her gifts (the benefit of which, however, is almost destroyed by the weakness of the government), consist of silk, grain, barilla, sulphur, olive-oil, wine, cantharides, sumach, manna, coral, rags, almonds, figs, raisins, nuts, anchovies, amber, goat, buck, and sheep-skins, pomegranates, oranges, lemons, &c., and pine apples of remarkable size and exquisite flavour. The chief port is Messina; next to this comes Palermo.

The exports of Sardinia are, chiefly, grain of uncommon excellence, tunny-fish, hides, barilla, and salt. Cagliari is the most considerable commercial city.

Corsica exports silk, olive-oil, and black, white, and red corals. The silk goes mostly to Genoa and Lyons, and the corals are sold at Marseilles, where they are manufactured and polished, to be sent to Africa, to be sold to the Moors and Negroes. The Corsican ports are Ajaccio, Bastia, and Porto Vecchio.

Malta, which is, like Gibraltar, a depôt for British and colonial goods that are to be disposed of in the Mediterranean, exports cotton, oranges, and other fruits.

The Ionian islands (Cephalonia, Zante, Corfu, Santa Maura, &c.) export wine, brandy, olive-oil, raisins, currants, citrons, melons, pomegranates, honey, cotton, and salt. The raisins and currants are superior to those of the Morea in quality. The wine is Muscadel.

The commerce of the island of Cyprus is inconsiderable. It exports cotton, wool, silk, wine, salt, turpentine, Turkish leather, &c. Its largest commercial cities are Larnica and Rhodes.

The exports of the island of Candia, which, by its situation, is designed for the mart of the European, Asiatic, and African trade, consist of oil, soap, wax, wine, linseed, raisins, almonds, laudanum, St. John's bread (the fruit of the *ceratonia siliqua*), &c.

The Kingdoms of the Netherlands and Holland.—The chief commercial cities of the Belgic Netherlands are Antwerp, Ghent, and Ostend. Antwerp was formerly the mart of the commerce of the North of Europe. The exports of Antwerp consist, principally, of wheat, beans, clover-seed, linen, laces, carpets, tapestry, and all the manufactures of Brussels, Mechlin, Ghent, and Bruges. The articles of export from Ghent are wheat, fine linen, flax, hemp, beans, &c.; those from Ostend are wheat, clover-seed, flax, tallow, hides, and the linen of Ghent and Bruges.

The chief exports of Holland, the commerce of which has revived since 1814, and employs every year a vast number of vessels of various descriptions, are butter, cheese, linen, cloth, drugs and paints, fish, wheat, linseed, clover-seed, geneva (gin), dye-stuffs, paper, &c. The principal commercial cities in Holland are Amsterdam, Rotterdam, and Groningen. Before the decline of Dutch commerce, Amsterdam was one of the greatest commercial cities of the world, the mart of goods from the East and the West, and from the principal states of Europe. At the time when the Dutch were in exclusive possession of the spiceries of the East, of the silks of the East Indies and China, and of the fine East India cotton goods, they dressed in coarse cloth, and were satisfied with a very frugal mode of living. The fine cloths which they themselves manufactured, they destined wholly for foreign countries, and, for their own use, purchased coarse cloth in England. At that time, they likewise sold the superior butter and cheese which they made, and, for their own use, bought the cheaper sorts from

England and Ireland. To the exchange and banking business, of which the channel was Amsterdam, the Dutch were also, in part, indebted for their great prosperity. With Hamburg, Amsterdam is yet the centre of the exchange business between the North and the South of Europe, although, from the time that the credit of the bank of Amsterdam diminished, this branch of business has declined, a great portion of it being transferred to Hamburg and London.—The imports are grain, wood, coal, tallow, wax, rags, &c. For the colonial trade of Holland, the possession of Batavia, Amboyna, Banda, Ternate, and Macassar, in the East Indies, is of importance, as are also the commercial settlements on the Coromandel and Malabar coasts, and those at Bantam, Padang, Japan, &c. In Africa, Holland has some forts in Guinea; in America she possesses Surinam, and the West India islands of Curaçao, St. Eustatia, and St. Martin.

Poland. The exports of Poland consist of corn, hemp, flax, lumber, linseed, tallow, and salt. Its commerce is inconsiderable, and is almost wholly in the hands of the Jews. Warsaw and Cracow are the two largest commercial cities. The former has two fairs every year. Cracow has a situation very favourable to commerce, but the principal article of its trade is furnished by the celebrated salt-mines of Wieliczka, situated in the neighbourhood. At the fairs of Leipsic and Frankfort on the Oder, Poland is supplied with manufactures, and all articles of luxury, in exchange for hare skins and other productions.

Portugal. The Portuguese exports are, chiefly, white and red Port wine, Lisbon and Calcavella wine, salt, oranges, lemons, and other fruit, cork, silk, wool, sweet-oil, &c. To this country are sent Port wine, Lisbon, Calcavella, Madeira, and Canary wines, salt, oranges, lemons, cork, &c.; in return for which the Portuguese obtain British manufactures and colonial goods, provisions, corn, meal, copper, lead, coal, &c. Their exports to the North of Europe are wine, salt, fruit, &c.; for which they receive hemp, flax, corn, iron, timber, tar, pitch, stock-fish, and Russian and German linen. The chief commercial cities are Lisbon, Oporto, and Setubal, commonly called St. Ubes. The foreign possessions of Portugal are, the cities of Goa and Dieu in the East Indies, together with a part of Timor, the factory at Macao in China, the Azores, Madeira and Puerto Santo in the Atlantic, the Cape Verd islands, those of St. Thomas, Angola, and some settlements in Guinea and on the western coast of Africa, with Mozambique, Melinda, and other settlements on the eastern coast.

Russia. Russia exports, principally, iron, hemp, flax, cordage of all kinds, tallow, hides, fir and oak timber, boards, planks, laths, spars, pitch and tar, together with all kinds of grain, especially wheat, linen, canvass of various kinds, wax, honey, bristles, suet, soap, isinglass, caviare, leather, train-oil, hempseed, linseed, and tobacco. The chief commercial cities are Tobolsk, Irkutsk, and Tomsk, in Siberia; Astrachan, Orenburg, and Kasan, in Asiatic Russia; Moscow and Novgorod, in the interior of Russia; Archangel on the White Sea; Libau (though very much decayed) in Couriand; Taganrog, Caffa or Theodosia, Odessa, Cherson, Sebastopol, and Azoph, on the Black Sea and the Sea of Azoph; Riga, Pernau, Narva, Revel, Petersburg, Viborg, Fredericshamm, and Arensburg; the places where the fairs are held, are Niznie-Novgorod, Irbit, &c., connecting the caravan trade of the East with the inland trade of European Russia, which is promoted by canals and rivers. By the Black Sea and the Sea of Azoph, Russia carries on a very lively trade with various Turkish ports; on the Caspian Sea, with Persia; by way of Kiachta, with China; and, on the north-west coast of America, it is at present laying the foundation of its trade in the Pacific. Russia has lately sent an expedition from Kodiak northward, to make topographical surveys in the interior of North America, and to establish a commercial intercourse with the natives of this unexplored country. Her colonies in North America are well provided for. Her officers are gaining nautical knowledge in England, and numbers have been sent to the United States of America, where models of nautical architecture and vessels celebrated for sailing have been purchased on Russian account.

Sweden and Norway. The articles exported from the twenty-eight Swedish ports are iron, steel, copper, pitch, tar, fir, alum, and fish. The chief commercial cities are Stockholm, Gottenburg, and Gefle. Carlscrona carries on considerable trade in iron, timber, pitch, tar, tallow, potash, linseed, &c., which articles are sent mainly to the French, Spanish, and Italian ports, commonly in exchange for salt. The exports of Gottenburg are fish, iron, steel, and boards. The institutions of Sweden for the promotion of commerce are the Bank, the East India Company, the West India Company, the Levant Commercial Company, the Association of Industry, &c. From Norway are imported fish, oak and fir timber, deal boards, masts, alum, vitriol, fish and seal-oil, pitch, hides, woollen stockings, iron, copper, and tar. The chief commercial cities are Christiania, Bergen, Drontheim, Christiansand, Drammer, and Stavanger.

Switzerland. Switzerland has a considerable foreign trade. Its exports consist, chiefly, of fine linen, silks, velvets, imitations of East India goods, and shawls, fine calicoes, clocks, watches, ribbons, wine, cheese, honey, &c. The most important articles of importation are colonial and East India goods, from Holland; salt, grain, wool, and cloths, from Germany; raw cotton, silk, &c., from Italy; manufactures of various kinds, from England; wine and brandy from France. The principal commercial cities of Switzerland are Basle, Berne, Zurich, Geneva, and Neufchatel.

Spain. For three centuries, with the decrease of the industry of Spain, its trade has been on the decline. This country might have monopolized the commerce of the world, if it had understood and improved its situation. The natural wealth of the soil is, nevertheless, still the prop of its trade. The most important productions are wool, silk, salt, iron, copper, coal, quicksilver, barilla, rice, saltpetre, sugar, almonds, olives, oranges, lemons, figs, wines, brandy, and fruit. In Segovia and Leon, about 1,000,000 arobas of fine wool are annually collected, of which about four-fifths are disposed of to the French, Dutch, and English. The excellent Spanish wines, brandy, fruit, barilla, &c., are profitable articles for the country. From the port of Barcelona, excellent silks, coarse cloths and cotton goods, with wine, brandy, almonds, nuts, and other productions, are exported; in return for which, the same port receives the silks of Lyons, the hosiery of Nismes, various kinds of stuffs and cotton goods, German linen and dried stock-fish from England, amounting to

about 3,000,000 dollars. The exports of Valencia consist principally of silk, barilla (soda), coarse wool, dried fruits, wine, and brandy. The latter is exported chiefly by the Dutch, and carried to Normandy and Bretagne. The English carry to Spain, chiefly woollen cloth; the French, linen, woollen cloth, cutlery, groceries, &c. From the port of Alicant, the Spaniards export, chiefly dried fruits, silk, wool, barilla, wine, Castile soap, olives, saffron, a kind of cochineal called *grana*, and salt; of which last, the English and Swedes annually take upwards of 9,000,000 pounds. In Carthagena and Malaga, also, much business is done. From the latter, wines, dried fruit, almonds, sumach, anchovies, olive-oil, &c., are exported. Cadiz has been one of the principal marts in the world, both in ancient and modern times. In 1792, its exports to the two Indies amounted to the sum of 276,000,000 reals, and its imports to upwards of 700,000,000 reals (8 reals make 1 dollar). Madrid, the royal residence, is likewise an important commercial place and depôt. Seville carries on a considerable trade in oil and oranges, which are exported from Cadiz. Almost the whole Spanish coasting trade is in the hands of the French, Dutch, and English. The independence of Spanish America has almost annihilated the colonial power of Spain.

Turkey. The Turks are as yet very far from being a commercial nation, although their commerce with Austria, France, Italy, Great Britain, Holland, &c., by means of the Jews, Armenians, and Greeks living in Turkey, who have the trade of this country almost wholly in their hands, is by no means insignificant. The insurrection of the Greeks did, indeed, at first interrupt very much the commerce of Austria and other states; and the British were also formidable rivals on the Ionian isles; but Vienna, the centre of the Greek trade, has nevertheless retained its connection with Turkey, while the productions and the demands of the free Greeks must soon much increase. They offer cotton for linen, silk for cloths, gold for iron. Nature and habit recommend to them intercourse with Austria. On the other hand, the commerce with European Russia, by way of Constantinople to Odessa, was very much restricted by the Porte, subsequently to 1823, by the necessity of relading, to which it subjected the European vessels destined for Odessa, and by other burdensome regulations. This, however, has been changed by the peace concluded with Russia in 1829. Every vessel can at present pass the Dardanelles unmolested. This must soon have a great influence upon the Turkish trade also. In the Archipelago, the Greek struggle for freedom has given rise to many dangers to the commerce of neutrals. The chief commercial place is Constantinople, particularly in regard to the trade with Russia. Till within a short period, it distributed the Russian products through the ports of the Mediterranean. The exports of this city, which under a wise and active government, might become the true mart of the world, are of such little importance, that the great quantities of goods, imported for the use of Turkey, have to be paid for, almost wholly with gold and diamonds. In this port, the English, French, Italians, and Dutch, obtain the produce of Poland, the salt, the honey, the wax, the tobacco, and the butter of the Ukraine; the hides, the tallow, the hemp, the canvass, the peltry, and the metals of Russia and Siberia, and in exchange, give the productions of their own countries. This business is transacted without the Turks having the slightest part in it.

Hungary, is considered by Austria as a foreign country, and is encircled in by a line of custom-house officers. The trade of Hungary therefore is under different regulations from that of the rest of the empire, and is any thing but favoured by the government. Its foreign commerce is, nevertheless, by no means insignificant. The exports are wine, tobacco, gall-nuts, antimony, alum, potash, horned cattle, wool, iron, copper, wheat, rye, and barley. The exports by far exceed the imports. Goods can only be introduced through Austria and Turkey, the government having prohibited every other way that might be selected for the purpose.

II. Asia. The commerce of Asia is mostly inland, carried on chiefly, in Western and Middle Asia, by means of those caravans (called by a poet, the *fleets of the desert*), in which, sometimes more than 50,000 merchants and travellers are collected, while the number of camels is far greater. The central point of this trade by caravans is Mecca, which, during the presence of the caravans, offers to the eye of the traveller a more active trade and a greater accumulation of merchandize than any other city in the world. The muslins and other goods of the East Indies, the productions of China, all the spices of the East, the shawls of Cashmere, &c., are transported on the backs of camels to Mecca, from whence they are scattered over, not only the Asiatic, but also the African continent.

The *Arabs*, who were, before the discovery of the passage to the East Indies around the Cape of Good Hope, the first commercial people of the world, have now no commerce of consequence. Coffee, aloes, almonds, the balsam of Mecca, spices, and drugs, and their African imports of myrrh, frankincense, and gum-arabic, are their chief articles of export. Yemen, rich in the costly productions of nature, resorts for a market to Mecca. The Arabian Gulf and the Red Sea connect the commerce of Arabia with that of Africa, especially with that of Egypt and Abyssinia.

From Masuah, in Abyssinia, are exported gold, civet, ivory, rhinoceros' horns, rice, honey, wax, and slaves; and for these the Africans obtain, in Mocha, or Mecca, and Jedda, cotton, cloves, cinnamon, pepper, musk, ginger, cardamom, camphor, copper, lead, iron, tin, steel, turmeric, vermilion, tobacco, gunpowder, sandal-wood, rice, hardware, arms, and a number of other kinds of European manufactures. The exports from Aden, an Arab city, on the straits of Babelmandeb, where many Jews reside for the purpose of trade, are coffee, elephants' tusks, gold, and various kinds of gums, especially gum-arabic; for which it imports chiefly East India and Chinese productions. Muscat, a port in the Arabian province of Oman, the key of Arabia and Persia, carries on considerable trade with British India, Sumatra, the Malay islands, the Red Sea, and the eastern coast of Africa.

Well adapted as the geographical situation of *Persia* is for commerce, it is pursued, nevertheless, with very little energy and little enterprise. Its exports consist mostly of horses, silk, pearls, brocades, carpets, cotton goods, shawls, rose-water, wine of Schiras, dates, wool of Caramania, gums, drugs of various kinds, &c. The chief places for Persian trade are the Turkish

cities of Bagdad and Bassora. The harbour of Abuschar, or Buschir, on the Persian Gulf, is also a mart for Persian and Indian goods. Bagdad, once the centre of a brilliant and extensive commerce, may still be considered as the great mart of the East, though it is by no means what it has been. From Bassora, the productions of Arabia, India, Persia, and the Asiatic islands are sent to Bagdad, where they find a very good market, and from whence they are scattered through the other cities of the Turkish empire. By means of the Arab caravans, Europe supplies Persia with goods of all kinds, and even with the productions of America. On the other hand, it has nothing to give but dates, tobacco, and a very moderate quantity of woollen stuffs, its whole trade consisting in the distribution and sale of the products of other countries. Bassora is, by its situation, the mart of the active East Indian, Persian, and Arabic trade, carried on in the Persian Gulf. Its trade with the East Indies is very considerable, it being the channel through which the Ottoman empire is supplied with the groceries of the East, and with the manufactures of the British possessions in the East Indies.

Asiatic Turkey. The principal port of the Levant is Smyrna, a very important depôt of the merchandize of the East and West. The articles exported from the Levant are coffee, cotton, wool, silk, madder, camels' and goats' hair, hides, raisins, figs, pearls, rotten-stone, whet-stones, nut-galls, opium, rhubarb, and other drugs. Angora sends to Smyrna by caravans, considerable quantities of Angora goats' hair, and stuffs made of the same material; for the Angora goats' hair is manufactured into camlet, in the Levant itself, and in Europe, especially in England, France, and Holland, some of whose camlet manufactories keeps agents in Angora, through whom they make their purchases. Damascus is the centre of trade in Syria, and does a good deal of business through the caravans, which go from the north of Asia to Mecca, and from Bagdad to Cairo. Aleppo has much commercial intercourse with Constantinople, Bassora, Bagdad, Damascus, and Scanderoon, or Alexandria, to which places caravans go every year through Aleppo. Its exports are its own silk and cotton goods, the shawls and muslins of the East Indies, the gall-nuts of Curdistan, copper, pistachio-nuts, and drugs. Alexandria has some trade of importance. Erzerum is the mart of silk and cotton goods, printed linens, groceries, rhubarb, madder, and East Indian zedoary.

The British East Indies, and the Malay Peninsula. For the long period of 4000 years, the products of India, so important in commerce, have remained the same; for all the commodities and treasures of India, mentioned by the ancients, are to this day, those for which the nations of the other quarters of the world resort thither, viz., rice, indigo, cochineal, and other dye-stuffs, opium, cotton, silk, drugs, cinnamon, cassia, cocoa-nuts, &c. The East India trade is mostly in the hands of the English, under the management of the East India Company. Next to the English, the United States are most extensively engaged in the East India trade. Denmark carries on but an inconsiderable trade with the East Indies, and that once carried on by Sweden is now almost annihilated, although, prior to the late great changes in the government of that country, the Swedish East India company was, of all the commercial societies of Europe, the best regulated, and the most successful in its operations, next to the English. The trade of Portugal with the British possessions in the East Indies is of importance; that of Spain, on the other hand, inconsiderable. Calcutta is the most important commercial city of the East Indies. Besides it, Benares, Guzerat, Oude, and Moultan, are worthy of note, among the commercial towns of northern India; Madras and Pondicherry, on the eastern coast; Bombay, Surat, and Cochin, on the western; Goa, &c. From Queda, on the peninsula of Malacca, are obtained tin, rice, wax, fish maws and sharks' fins; at Salengore, Pahang, and Trangano, cloves, nutmegs, pepper, camphor, betel, ivory, gold dust, tortoise-shell, tin, &c. Gold dust is exported chiefly from Malacca. Since 1819, the British government in Calcutta, through Sir Thomas Stamford Raffles, has founded, according to his plan, a new commercial town on the fertile, well-wooded island of Sincapore, on the south extremity of the peninsula of Malacca, on the straits of this name, which is of extreme importance to the British trade with China. and must destroy the China trade of the Dutch. If Sincapore is made a free port, Great Britain will be able to supply from thence the more distant parts of India with the productions of its industry.

China. The trade which China carries on with Europe, British India, the United States of America, Cochin-China, and Siam, with Japan, and the other Asiatic islands, is very considerable. The British imports into China are partly shipped by the East India Company, partly by private merchants. From 1781 to 1791, the company sent thither to the amount of 3,471,521*l.* in goods, and 3,588,264*l.* in bullion; from 1792 to 1809, 16,502,338*l.* worth of goods, and 2,466,946*l.* in bullion. The exports which the company made to England, amounted from 1793 to 1810, including duties, freights, &c., to 41,203,422*l.*, and they were sold for 57,896,274*l.*, leaving the company a net profit of 16,692,852*l.* From the different ports of the British possessions in the East, 35 ships entered the port of Canton in the years 1818 and 1819, and the value of their cargoes was 8,714,272 dollars, and including what was shipped to Macao, the total was 11,999,272 dollars. The exports of the English merchants not connected with the company, to China, probably amount annually to 500,000*l.*—Next to the English, the people of the United States have the most trade with China. Its amount has increased 387 per cent. in 25 years. The exports of tea by the East India Company, in this time, have also greatly increased. The company's export trade from Europe to China has long been stationary. The imports of the nations on the continent of Europe into China consist chiefly of gold bullion, for which tea is received; but these imports are small, since most of them obtain their tea from the English and Americans. With Siam, Cambodia, Cochin-China, the Asiatic islands, and Japan, China has a very active intercourse, and of late, with Russia also, both by land through Kiachta to Irkutsk, &c., and by water. The Dutch, English, and Americans have factories at Canton, the French an agent there or at Macao, the Spaniards an agent at Macao, where the Portuguese have a colony.

From Siam and Tonquin are exported tin, ivory, diamonds, and other precious stones, gold dust, copper, salt, betel, pepper, wax, silk, timber, and lackered wares, and the commerce of these two

countries is mostly in the hands of the Chinese and Portuguese. The trade of Cochin-China is mostly in the hands of the Chinese. The exports are sugar, silk, gold, betel-nuts, ebony, Japan-wood, buffaloes' horns, dried fish, and fish-skins. The Chinese empire is so vast, and the variety of the products of the different provinces so great, that the inland commerce of this world in itself has withdrawn the attention of the people from the foreign trade, which oppressive regulations have injured. Formerly, however, Chinese vessels went to Arabia, and even to Egypt.

Japan. Since the expulsion of the Portuguese from Japan, the commerce of this country has been almost wholly domestic. The only foreigners with whom the Japanese still have any trade, are the Chinese and the Dutch, and these are limited to the single port of Nangasaki. The Chinese supply the Japanese with rice, common porcelain, sugar, ginseng, ivory, silks, nankeen, lead, tin plates, alum, &c.; and in return, receive copper, camphor, lackered wares, pearls, corals, and a metallic composition, called *sowas*, consisting of copper and a small quantity of gold. The Dutch obtain chiefly copper, camphor, lacker, and lackered wares. Only two Dutch, and 12 Chinese vessels are allowed to enter the harbour of Nangasaki annually. After the arrival of a vessel and the performance of the preliminary ceremonies, the goods are sent on shore. Then come the imperial officers (for the trade with foreign countries is the monopoly of the emperor), who examine the quality and the quantity of the goods, deliberate together, and fix the price of the native commodities that are demanded in return. Foreigners must submit to these conditions, or keep the goods which they have brought. The Japanese merchants can obtain foreign goods only by purchasing them of the emperor. In the manufacture of silks and woollens, porcelain, and lackered wares, the Japanese are in no degree inferior to the Europeans. In the manufacture of hardware, they have also attained great skill. The Japanese sabres and daggers are very excellent, and are perhaps surpassed only by the sabres of Damascus. In polishing steel and all other metals, they are also very skilful, and their fine porcelains are much superior to the Chinese. In the beginning of the 17th century, the English began to trade with Japan; but the Portuguese missionaries, and afterwards the Dutch, succeeded in prejudicing the government against them. In 1673, the attempt to renew the trade was again frustrated by the Dutch. On account of the great advantages which it was thought this trade would ensure to England, a third attempt was made in 1699, and the factory at Canton was instructed to enter into connection with Japan, if by any means possible. The result, however, did not satisfy expectation, and all farther attempts have been given up. In 1813, however, when Java was subjected to Great Britain, the East India Company had some slight intercourse with Japan. The Russian mission to Japan, under Krusenstern, in 1805, was no less unsuccessful than the English had been.

The Islands of Amboyna, Banca, the Bandas, Java, Sumatra, Borneo, &c.—From Amboyna are exported cloves, to confine the cultivation of which solely to this island, the Dutch took great pains to extirpate all the clove-trees on the neighbouring islands. For this purpose, also, the government of Amboyna, with a numerous retinue, still makes a journey every year to the other Dutch islands. Banca is celebrated for its tin mines, and the exportation of this tin to China is of much importance, as the Chinese prefer it to the English on account of its malleability. About 4,000,000 pounds of tin are obtained annually. The Banda islands produce nutmegs and mace. The staple exports from Batavia, where all the goods of the Dutch East India company are deposited, are pepper, rice, cotton, sugar, coffee, and indigo. 6,250,000 pounds of pepper, part of which is raised on the island itself, part brought from Bantam, Sumatra, Borneo, and the other islands, are annually stored in the magazines. Both coffee and sugar have also been cultivated here, of late years, to the amount each of 10,000,000 pounds. Borneo has, besides pepper, gold in dust and bars, wax, sago, camphor, the last of the most excellent quality. In addition to the Dutch and English, the Chinese have here an active trade. The exports of Ceylon are cinnamon, pepper, coffee, tobacco, betel, cocoa-nuts, drugs, timber, pearls, precious stones, corals, &c. Of the Philippines, the principal are Lucon or Manilla, and Magindanao or Mindana. The exports are indigo, sugar, silk, gold dust, quassia, pepper, tortoise-shell, wax, precious stones, silver, sago, and tobacco. The trade of the Philippines with China and South America is considerable. Manilla produces sugar, the best Asiatic tobacco, indigo, and a kind of hemp. The Prince of Wales' Island, from its situation between India, China, and the Eastern isles, has an important trade. Its exports are chiefly benzoin, pepper, betel-nuts, groceries, metals, East India zinc, cochineal, eagle-wood, Japan-wood, elephants' teeth, sugar, and silver bullion. Sumatra carries on considerable trade. The exports are gold dust, betel, benzoin, pepper, camphor, Japan-wood, sulphur, rattans, wax, gum-lac, groceries, tin, &c.

III. Africa. The want of navigable rivers, and the immeasurable deserts by which the fruitful regions of Africa are separated, form an insurmountable obstacle to that extension of commerce which the great fertility of this quarter of the globe would promise. In addition to the intercourse of the interior, the commerce of Africa has its sources in Egypt, the Barbary states, on the west coast in Guinea, in the neighbourhood of the rivers Gambia, Niger, and Senegal, at the Cape of Good Hope, and the Portuguese colonies, and on the coasts of the Red Sea. The inland trade is carried on by means of caravans. The African caravans consist of from 500 to 2000 camels. The three principal countries from which they proceed are Morocco, Fez, and Egypt. The chief articles of the inland trade of Africa are salt, gold, and slaves. The greatest caravans go from the western coast and from the interior by way of Timbuctoo, the great mart of the inland trade, and other places of depôt, to the eastern coast, where the most important commercial places are Natal (on the coast of Lagoa), Soffala, Quilimane, Mozambique, Querimba, Quiloa, Mombaza, Melinda, Brava, Magadoxo, Berbera, Zeila, and Adel. Quilimane, Mozambique, and Melinda, are Portuguese settlements. From Adel, Zeila, Berbera, and Brava, are exported, mainly, gold dust, ivory, and incense, for which the products of Arabia and the East Indies are returned. There is a considerable trade between the British settlements in the East Indies and Mozambique, and the English obtain elephants' and hippopotamus' teeth, tortoise-shell, drugs, cowries, gold, &c.

The Barbary States. The commercial intercourse of the Barbary states with Europeans is very inconsiderable and vacillating, and the little business which is transacted is mainly in the hands of the French, British, and Americans. The exports consist of olive-oil, wax, wool, wheat, gums, almonds, dates, aromatic seeds, ivory, leather, hides, and ostrich-feathers. Even the coral fisheries on the coasts (from Cape Rosa to Cape Rouax) are in the hands of the French and Italians; and the annual produce of about 50,000 lbs. of coral is worth more than 420,000 dollars. But a far more important commerce is pursued by the Barbary states with Arabia, Egypt, and the interior of Africa. Their caravans are met with in Mecca, Cairo, and Alexandria. The chief commercial cities are Algiers, Tunis, Tripoli, Sallee, and Agadeez, or Santa Cruz, and in Morocco, Mogadore. Before the French revolution, the commerce of Algiers was wholly in the hands of a company of French merchants at Marseilles, who had regular settlements in the ports of Bona, La Calle, and Il-Col. But, in 1806, the dey conveyed, for 50,000 dollars, the possession of those ports to England. The chief ports of export of Algiers are Bona and Oran. Tunis is the most important commercial state in Barbary. Its chief harbours are Biserta, Susa, and Soliman. Tripoli has little trade, and its exports consist mostly of saffron, ashes, senna leaves, and madder. The trade of Morocco and Sallee is also of little importance. Agadeez, or Santa Cruz, is the most southerly harbour of Morocco, and was once the centre of a very important trade. Fez is still such a centre between the ports of Morocco, the Mediterranean Sea, and the interior of Africa.

Cape of Good Hope. The trade with the Cape of Good Hope is extremely advantageous to Great Britain. In 1809, the importation of English goods exceeded 330,000*l.*, while the exports of the colony (mostly Cape wine) did not amount to 6,000*l.* The amount of the trade has since been very much enlarged by the increase of colonization. The average exports from Great Britain to the Cape of Good Hope amounted to 2,119,000 dollars, and the imports into England from the Cape to 1,561,000 dollars.

Egypt. From its uncommonly favourable situation, in the centre of three portions of the globe, this country seems destined by nature to be also the centre of their commerce; but it has altogether lost its former high rank in the commercial world, since it has ceased to be the channel of the India trade. It has, nevertheless, considerable inland trade, which extends into the interior of Africa. Three caravans go thither, every year, from Egypt. One goes to Sennaar, and collects the productions of this country and Abyssinia; another to Darfour, and the third to Fez, whither the productions of Bornou, and all the countries lying along the Nile, are brought. Other caravans exchange Egyptain commodities for those of the East Indies and Arabia. But the most considerable is that which consists of the united caravans of Abyssinia and Western Africa, and goes annually to Mecca. The exports of Egypt are rice, corn, cotton, myrrh, incense, opium, dates, mother-of-pearl, ivory, gums and drugs of various kinds, hides, wax, &c., most of which go to Constantinople, the Barbary states, Great Britian, Venice, and Marseilles. It also exports the productions of Arabia. The chief commercial cities are Cairo and Alexandria, united by a complete canal since 1819. Cairo has two ports, Rosetta and Damietta. France sends to Egypt woollen cloth, red caps, fringes of all kinds, and ornaments of dress, ordinary china ware, arms, &c. England sends muslins, and cloths of different kinds, alum, iron, lead, vitriol, gums, &c. From Florence silks are imported.

Guinea. Sierra Leone, and the Pepper, Ivory, Gold, and Slave Coasts, where the Dutch, French, English, and Danes have settlements, export gold dust, ivory, gums, hides, &c., and formerly slaves, in exchange for woollen and cotton goods, linen, arms, gunpowder, &c. The coasts of Lower Guinea (Congo, Angola, &c.), and the Guinea Islands, mostly occupied by the Portuguese, export grain, provisions, cotton, indigo, sugar, &c. The slave trade is here prosecuted still by the Portuguese.

Among the other *African Islands*, the Azores raise, for exportation, wine and fruits. About 20,000 pipes of the former are annually exported by the English and Americans, chiefly to the East and West Indies. The Island of St. Michael sends, every year, to England and the United States, 60 to 80,000 boxes of oranges. The oranges of the island of Pico are remarkable for their superior quality. This island also produces a beautiful kind of wood, which is almost equal to mahogany. The staple productions of the Canaries are archil, in its raw state, rosewood, brandy, and Canary wine. The last goes chiefly to the West Indies and England: in the latter country it is always sold for Madeira wine.

The Cape Verd Islands export archil in a raw state, and coarse cotton cloth for the use of the Africans. The staple produce of Madeira is valuable wine, which is divided into five kinds, according to the market for which it is designed. The most excellent is called *London particular*. The next in quality is also sent to the London market. Of inferior quality is that destined for the India market. The kind that goes to America holds the fourth rank, and the fifth is designated by the name of *cargo*. Of this wine the English annually receive more than 7000 pipes; the United States about 3000. The Isle of Bourbon produces coffee, cloves, white pepper, cotton, gums, benzoin, and aloes. Its trade is confined almost wholly to Madagascar, Isle de France, the Comoro Islands, and the settlements of the Arabs on the eastern coasts of Africa. The Isle de France, or Mauritius, exports coffee, indigo, cotton, sugar, nutmegs, cloves, ambergris, &c. The exports of Madagascar are cowries, betel-nuts, ambergris, wax, cocoa-nuts, and corn.

IV. America. The extensive coasts of America give it all the commercial advantages of the ancient world, free from the obstacles presented by those masses of continents, the interior of which is so remote from the sea, and destitute of navigable rivers, like the whole of Africa and the boundless tracts of Asiatic Tartary and Siberia. In the abundance of navigable rivers, both North and South America have an immense advantage over the other quarters of the world. The long chain of great lakes and numerous navigable rivers in North America are already the theatre of a very active commerce. The great inland countries of South America are rendered accessible by rivers of gigantic magnitude, and from the mouth of the River Plata to the Gulf of Darien, an inland navigation may be effected, almost without having recourse to the aid of art. But there still remains, for the promotion of American commerce, the execu-

tion of a great work—the digging through the narrow isthmus of Darien—by which a connection between the Pacific and Atlantic would be effected, the advantages of which would be incalculable. The western passage to India, which Columbus sought for, would then be effected. Alexander Von Humboldt points out three places as most adapted to the execution of such a project. Nature herself seems willing to assist, for, though the mountains forbid the idea of forming a canal immediately across the isthmus, yet, by starting in lat. 12° N., joining the head of lake Nicaragua to a small river which runs into the Pacific Ocean, and forming a canal 30 miles long, through a low level country, a communication between the two oceans might be effected. The governments which are most directly interested in making such a canal are at present too weak and too unsettled to be able to carry it into effect; yet Bolivar appeared to have always had this great work in view.

The United States of North America. The rapid progress which the United States have made in commerce and navigation is unparalleled. Hardly had this people appeared on the ocean before every coast of the earth was visited by their navigators. While they are seen covering the ocean with their vessels throughout the Atlantic coast, even to Cape Horn, whence they enter the broad Pacific; in the other direction, they press on to the ice of the North Pole, and penetrate the deep recesses of Hudson's Bay and Davis's Straits. The most remote and dangerous seas are traversed by their keels. The coasts of the whole southern hemisphere, the western coast of America, and the eastern coasts of Asia, are visited by them. It is a very common thing for an American merchantman to make a voyage round the world, starting from the United States, going round Cape Horn to the north-west coast of America, taking in furs, sailing to China, and going from thence with tea, &c., to the ports of Europe. The American whalers are distinguished for skill and boldness.

Agricultural Exports. The trade of the United States, for the year ending September, 1828, may be assumed as the basis of the remarks to be made upon the subject of this commerce. The exports of domestic products for that year, according to the custom-house estimates, were 50,669,669 dollars. Those of cotton, the great staple of the country, were 22,487,229 dollars, and, accordingly, nearly half of the entire amount. The next greatest export is that of tobacco, which amounted to 5,269,960 dollars. Of rice, the export amounted 2,620,696 dollars. The value of these three articles, being over 30,000,000 dollars, thus constituted three-fifths of the whole. In the annual returns made to Congress, the exports of domestic products are divided into those of the *sea*, the *forest*, *agriculture*, and *manufactures*. The three species of agricultural articles above mentioned are mostly the productions of the Southern States, including Virginia and Kentucky. The other exports, coming under the same head, are mostly furnished by the Middle and Western States: namely, beef, tallow, hides and cattle, butter, cheese, pork, bacon and hogs, horses, mules, sheep, flour, biscuits, corn-meal, rye-meal, oats, potatoes and apples, flax-seed, and hops. Of these articles, the principal is flour and biscuit, the value of which was 4,464,774 dollars, being the third article in value among the exports. The fifth article in value is that of swine and their products—viz., bacon, pork, and lard, the value of which was 1,495,830 dollars, making about one thirty-third part in value of the whole export. The articles of corn-meal and rye-meal amounted to 881,894 dollars, constituting a little more than one-sixtieth part of the whole exports. Cattle and their products, including butter and cheese, exceeded the last amount, being 896,316 dollars. This species of export is of far less comparative importance in the trade than formerly, being limited to its present amount, not by the capacity for production, but by the extent of demand in the foreign markets; for an increase of the foreign demand would very soon double and treble the quantity. Some of the articles comprehended in the above list, though agricultural products, yet involve some process of manufacture; such, for example, as butter, cheese, bacon, flour, biscuit, meal, and part of the tobacco. A great many, however, of the exports coming under the head of *manufactures*, include in them the value of materials supplied by agriculture, such as the cotton fabrics, those of leather, and spirits distilled from grain; so that, on the whole, the strictly agricultural products of the country constitute a larger proportion of the whole exports than the tables represent; and yet the proportion represented by the tables is very large, being 38,500,000 out of the 50,000,000; and, if we add the value of the materials supplied by agriculture for the manufactured exports, we shall have at least six-sevenths of the whole domestic exportation, consisting of the raw products of agriculture.

Products of the Sea. The products of the whale, cod, mackerel, and herring fisheries, exported mostly from the Northern States, amount to 1,693,980 dollars, being nearly a thirtieth part of the whole domestic export. Nearly one-half of this value consists of codfish, and more than one-third of the products of the whale-fisheries.

Products of the Forest. The value of skins, furs, ginseng, lumber, staves, bark, tar, pitch, rosin and turpentine, and pot and pearl ashes, partly from the Northern and partly from the Southern States, which were formerly of much greater comparative importance in the trade of the country, now constitutes about one-thirteenth part of the whole value of the domestic exports, and amounts to 3,889,611 dollars. A large proportion of the trade in these articles, as well as in those of codfish and bread-stuffs, is carried on with the West Indies, Mexico, and South America. The skins and the furs go to Europe and Canton; the ginseng to Canton, but in less quantity than formerly, being, in 1828, but 91,164 dollars; and the pot and pearl ashes are sent to England and France.

Manufactures. The manufactures are, as yet, of the coarser sort, consisting partly of articles made of the products of the country, and partly of those fabricated from foreign materials. But it is obvious that the arts of the country, in their early stages, will be most naturally directed to the working of the raw materials of domestic production; and we accordingly find, that a very small part of the value of exported manufactures consists of the cost of raw materials previously imported. The articles in which the foreign materials form a considerable part of the value are spirits manufactured from molasses, refined sugar, articles of iron, cordage, chocolate, gunpowder, umbrellas and parasols, gold and silver coin, and jewellery.

The whole estimated value of exports of home manufactures is about 6,500,000 dollars, being about 13 per cent. of the whole domestic exports of the country. About 700,000 dollars of this amount ought to be struck out of the list of domestic exports, being gold and silver coin, consisting mostly of metals imported from abroad, and, after being coined at the mint, again exported. The labour put upon these materials, in coining, is so inconsiderable a part of their value, that the value of the coin of the country exported ought not to be included in the estimate of the value of domestic exports. Considerable quantities of gold, it is true, have been produced in North Carolina, but by no means enough, as yet, to supply the demand for the consumption of the country, though it is to be considered, at the same time, that this article, as far as it can be supplied from the domestic mines, will tend directly abroad, being drawn into this channel by the higher price of gold, compared with silver, in England and France than in the United States; the value being in England, at $15\frac{6}{10}$, in France as $15\frac{66}{129}$, and in the United States, as $15\frac{11}{27}$ to 1. Consequently, the gold, whether in coin or bullion, tends strongly to leave the country. Some of it is arrested for use in jewellery and the arts, but very little in the currency or in the vaults of the banks. Omitting this article, then, the other articles above enumerated, being the only ones the value of which is made up, in any considerable degree, of foreign materials, are valued in the returns, at 683,000 dollars. The value of materials imported, and then wrought up in manufactured articles, and exported, and included in the list of domestic manufactures, may be estimated at about 200,000 or 250,000 dollars; leaving the net exports of manufactures from the raw products supplied by the country about 5,750,000 dollars. As cotton fabrics form a large item in this list of exported manufactures, and those fabrics are mostly of the coarser kind, the raw material will constitute a very considerable part of their value, and the proportional value of the direct wages of manufacturing labour, incorporated in these exports, will be proportionally less. If, for instance, a plough, or trunk, or quantity of combs, be sent abroad, almost the whole value of the export consists of the wages of the manufacturers; and a still greater proportion of the value of earthen and stone wares, which make a very considerable item in this list, is of this description; whereas an export of spirits distilled from West India molasses comprises a comparatively small proportional value of manufacturing labour. Taking the whole list of domestic manufactured articles together, and making allowances for the cost of the raw materials, in their rudest state, after they are taken from the ground or from animals, and assume the character of merchandize, by deducting their value from the gross amount of that of the exported manufactures, the remainder, which is the result of the manufacturing labour, interest of capital, and profits incorporated into these materials, to bring them into the state in which they are exported, may be estimated at about 4,000,000 dollars. We will now glance hastily at the descriptions of articles on which the arts of the United States are employed for the supply of foreign markets; and the most considerable of them is cotton twist, thread and fabrics, the exported value of which, for the year 1828, was 1,000,000 dollars and a fraction over, being one-fiftieth part of the whole domestic exports, the principal markets of which are South America, Mexico, and the Mediterranean. The value of leather, and its various manufactures, exported, is a little over 500,000 dollars, making one per cent. of the entire exports of the description of which we are speaking. The value of hats exported during the same year was about 333,300 dollars—a very large amount, considering the short period since this article has been sent to foreign markets. Soap and candles have long been supplied for the foregin markets, the amount for the year in question being about 900,000 dollars. The various articles manufactured, for the most part, of wood, such as furniture, or of wood, leather, and iron, such as coaches and carriages, besides various agricultural implements supplied to the West Indies and South America, constitute a very important branch of trade, which amounted to between 600,000 and 700,000 dollars. The American glass begins to appear in the foreign markets. The value sent abroad in 1828 was 51,452 dollars, and it bids fair to be increased. The other exports consists of a variety of articles in small quantities, among which are, wearing-apparel, combs and buttons, brushes, fire-engines and apparatus, printing-presses and types, musical instruments, books, maps, paper and stationary, and trunks. It is apparent, from the above enumeration and estimates, that the manufactured articles, of which the export is most considerable and the most flourishing, are those of which the raw materials consist, mostly, of cotton, wood, and leather.

Foreign Exports. The foreign articles imported and again exported from the country, during the same year, amounted to 21,595,017 dollars. This transit trade thus appears to form a very important part of the American commerce. But one-third of this whole amount consists of an article which affords very little freight, namely specie, the export of which during the same year, was about 7,500,000 dollars. Another large item in value, of this transit trade, consists of cotton fabrics, the exports of which were 2,000,000 dollars. The foreign silks exported amounted to about a quarter as much. The value of wines exported was about 333,300 dollars; that of teas about twice as much; and that of coffee and cocoa 1,500,000 dollars, and of sugar nearly 1,000,000 dollars. These are the most important articles of foreign export. The other exports of foreign articles previously imported amounted, during the same year, to about 8,000,000 dollars in the whole; but it is not necessary to enumerate them.

Imports. The imports, for the same period, according to the custom-house estimates, amounted to 88,589,824 dollars, and exceeded the estimated value of the exports by about 16,250,000 dollars. There should, of course, be an excess of value of imports, according to those returns, whether their value is estimated at the cost in foreign ports, or at the market-price in the American ports; for these goods are the returns for the exports, the value of which is estimated at the rate of the markets in the United States: and unless a greater value of merchandize can be obtained in exchange, in the foreign ports, the ship-owners would obtain nothing for outward freight: and still more ought the value of the imports in the American markets, after deducting duties, to exceed that of the exports; for this excess is the only fund for paying the two freights and interest on the capital employed. This excess, for the year in question, was about 22 per cent., which cannot, however, be considered very exact, but is probably below the actual rate. That

it must be a large amount, in order to save the merchants from loss, is evident; for the registered tonnage, which is mostly employed in foreign trade, is about 750,000 tons, so that an excess of 16,000,000 dollars in the value of imports over that of exports, supposing an exchange of one for the other, would give only about 21 dollars per ton, per annum for the shipping employed—an amount scarcely sufficient to defray the expenses of the navigation, including port-charges, and leave a surplus for interest on the capital invested in the cargoes, and a small profit to the merchant. But the rate per ton for the shipping actually employed in the foreign trade, if we estimate the accession at 16,000,000 dollars, and supposing the whole trade confined to American ships, will exceed that above mentioned, since the registered vessels are partially employed in the coasting-trade, as vessels often take a cargo from one-home port to another, whence a cargo is taken for exportation. But a part of this trade requires none of the excess, of which we have been speaking, to defray the expenses of navigation, for about one-thirteenth part in value is carried on in foreign bottoms, the imports in which were about 6,500,000 dollars. If the whole trade were carried on by foreign shipping, and the whole were a barter trade, without credits, as the trade between any two nations, or any number of nations, must in effect be, in the long run, the value of exports and imports, estimated at the prices in the home market, after deducting duties paid on importation, must be just equal; for in the case supposed, all the expenses of transportation are defrayed by the foreign ship-owners. In proportion, therefore, as foreign shipping is employed in the trade, the excess of the value of imports over that of exports will be reduced; since, if a country employs foreign shipping in its trade, it must export an additional value of merchandize to pay the freights, or import a smaller value of merchandize in exchange for the same exports. In regard to the various kinds of goods imported, without pretending to great exactness, which is the less important as the proportions vary considerably from year to year, it appears that some of the principal articles have constituted nearly the following proportion of the whole imports, previously to 1828; viz.—wool and woollen fabrics, 11 per cent.; cotton stuffs, 12; silk, 10; hemp and flax, and manufactures of them, 5; iron and steel, and manufactures of them, 5; spirits, 1¼; molasses, 2½; teas, 4; coffee, 3½; sugar, 5½; and indigo, 1½ per cent.

The principal trade, both import and export, is with Great Britain and its dependencies, whence, in 1826, the imports were forty-two ninety-sixths of the whole importation. But to state, even in a general manner, the species of merchandize of which the commerce to and from each country principally consists, would extend this part of the present article to too great a length. Before closing it, however, we should not omit to remark, that the domestic trade of the country is more extensive and more important than the foreign. That it is more extensive, appears from the returns of the shipping, a greater quantity of tonnage being employed in the coasting trade and fisheries than in the foreign commerce; and as these vessels make from 3 to 10, 12 or 20 passages in a year, according to the distance of the ports between which they trade, the amount of commercial exchanges along the coast, and up the rivers to the head of sloop navigation, without including the trade between the coast and the interior, must greatly exceed the foreign commerce.

From the official report of the treasury department, it appears, that the imports into the United States, during the year ending September 30, 1829, amounted to 74,492,527 dollars, of which amount 69,325,552 dollars were imported in American vessels, and 5,166,975 dollars in foreign vessels; that the exports, during the same year, amounted to 72,358,671 dollars, of which 55,700,103 dollars were of domestic produce, and 16,658,478 dollars of foreign produce; that of domestic articles, 46,974,554 dollars were exported in American vessels, and 8,725,639 dollars in foreign vessels; and of the foreign articles, 15,114,887 dollars were exported in American vessels, and 1,543,591 dollars in foreign vessels; that 872,946 tons of American shipping entered, and 944,799 cleared, from the ports of the United States; and that 130,743 tons of foreign shipping entered, and 133,006 cleared, during the same period.

THE CANADAS, NOVA SCOTIA, AND NEW BRUNSWICK. The trade of the two Canadas was long confined to the bare produce of the fisheries and the fur trade. But, in consequence of the improvement of the British colonial system, and of the embargo which was imposed on the American trade during the last war of the United States with Great Britain, it has much increased. Its exports are wheat, flour, corn, biscuit, fish, oak and pine timber, staves, masts, lumber, Canadian balsam, spruce-beer, pot and pearl ashes, cast-iron, furs and skins, castoreum, ginseng, &c. The imports are wine, rum, sugar, molasses, coffee, tobacco, salt, coal, and British manufactures. Since 1825, the trade of Canada has increased rapidly. The trade is mostly with the British West India colonies and with the mother country. They do some business, however, with the United States. The trade which they have with the Indian tribes, consists merely of barter.—Nova Scotia, and New Brunswick, have nearly the same exports.

MEXICO. The commerce of Mexico is at present checked by natural and political causes. The want of river communication is a great impediment to its internal commerce. Roads lead from the *plateaux* to the seaports, but they are very imperfect, and beasts of burden, therefore, are preferred to carriages, which would not be able to make their way. The principal objects of export are gold and silver, either in bullion, coined, or worked up in various ways; cochineal, sugar, flour, indigo, salt meat, dried vegetables, tanned hides, sarsaparilla, vanilla, jalap, soap, Campeachy wood, and pimento of Tabasco. Among the articles imported are woollen cloths, silks of Lyons, linen from Germany, white and printed calicoes from France, England, and the United States, paper, china, spirits, cacao, quicksilver, iron, steel, wine, wax, jewellery, watches and clocks, and all kinds of ornaments. In 1826, 1267 vessels entered the ports of the republic. The chief port of Mexico is Vera Cruz. Mexico, the capital, is a commercial place, as we might easily suppose to be the case in a country in which very little is manufactured, and which is so fertile. A part of the commerce of the United States with Mexico is carried on by means of caravans, which go from the state of Missouri to Santa Fé, in Texas. The smuggling trade in Mexico is very great. The chief commercial cities of Mexico are Acapulco and Vera Cruz. Acapulco, or Los Reyes, carries on

a considerable trade with the Philippines, and the coasts of Quito and Peru. To Manilla a galleon used to be sent from this port every year, freighted with silver, cochineal, cacao, sweet-oil, Spanish wool, and European toys. This brought back muslins, printed linen, silks, Chinese goods, groceries, spices, and precious stones. Guatimala is celebrated for its indigo, which is noted for its hardness, lustre, and weight.

South America. South America has many articles of trade. The mineral treasures of the country are boundless. In the 16th century, gold and silver existed in such profusion, that, for 25 years, 13,000,000 dollars are said to have been annually exported to Spain from Peru alone, exclusive of what was sent in bars. These precious metals are found throughout Peru, Chili, and the upper section of Tucuman, especially in the Cordilleras; but, in addition to gold and silver, this immeasurable chain of mountains affords copper, lead, iron, and platina. The richest mines of South America are those of the province Las Charcas, in the territory of the former viceroyalty of Buenos Ayres. There are, in that district, 30 gold mines, 27 silver mines, 7 copper, 1 tin, and 7 lead mines. The richest of these mines are those of Potosi, which are situated near the sources of the La Plata. Acosta's account, that, during 40 years that the mines had been wrought, they had yielded 12,000,000,000 dollars, is much exaggerated. But we gather from official reports, that, from the time of the discovery of America till 1538, the fifth part, accruing to the king, of all the silver obtained from the mines of Potosi, and registered, amounted to 395,619,000 dollars; so that, when 39 years had elapsed from the discovery of America, 41,255,043 dollars were obtained annually, exclusive of the considerable quantities which undoubtedly were conveyed from the country secretly, and without the payment of duties, and of that which was used for making silver vessels, images, and ornaments for the monasteries and churches, which must have amounted to an immense sum, since all the religious establishments in the country, and especially in the city of Potosi, were very rich in silver vessels. But, whether owing to the exhaustion of the mines themselves, or the faulty management of them, the profits have since diminished. The other exports from South America, although the Spanish and Portuguese directed their chief attention to the obtaining of metals, are very considerable. The following are the principal: cochineal, indigo, cacao, the Peruvian bark, hides, ox horns, tallow, wax, cotton, wool, flax, hemp, tobacco, sugar, coffee, ginger, pimento, jalap, sarsaparilla, ipecacuanha, guaiacum, dragon's blood, and various other medicinal gums, dye-wood, ebony, mahogany, emeralds, various kinds of balsams, &c.

The chief commercial cities of South America are Rio Janeiro, Buenos Ayres, Lima, Carthagena, Caracas, Potosi, and Bahia. Buenos Ayres was in possession of the transit trade of all the Spanish possessions in America, and, before the beginning of the revolution, was the mart of the trade of the mother country and its colonies. The principal source of gain for Caracas is the cacao plant, as it supplies nearly two-thirds of the European demand. The hides and skins which it exports are superior to those of Buenos Ayres; and the rich ore from the copper mines of Aroa is superior to the Swedish, or to that of Coquimbo, in Chili. The internal trade of South America, especially between Buenos Ayres and Peru, is very considerable. That with the Indian tribes is chiefly in the way of barter; axes, knives, scissors, swords, necklaces, mirrors, and coarse cotton and woollen goods, being exchanged for the productions of the country, especially the celebrated Paraguay tea, and some fine furs.

Brazil has three great commercial cities—Rio Janeiro, Bahia, or St. Salvador, and Pernambuco. The exports are, chiefly, cotton, indigo, sugar, coffee, rice, tobacco, tallow, mahogany, Peruvian bark, ipecacuanha, hides, gold, cacao, vanilla, the diamond, the topaz, chrysolite, amethyst, and other precious stones, and a great variety of dye-stuffs, balsams and gums, dried beef, and India-rubber shoes. The greater part of the Brazilian trade is in the hands of the English. The imports are iron, steel, copper utensils, salt, woollen cloths, linen, calicoes, hats, shoes of all kinds, china, glass-ware, trinkets, books, paper, watches, clocks, and particularly East India goods, such as are not raised in Brazil. Portugal sends to Brazil wine, oil, spirits, hats; the United States, send flour, turpentine, and furniture. Naval munitions, sailors' clothes, and arms, are likewise imported.

Colombia, consisting of Venezuela and New Grenada, says Alexander Humboldt, has received from nature a greater and richer variety of vegetable products, suited for commerce, than any other country of Spanish America; yet its commerce has been declining every year since its separation from Spain. In Colombia, Peruvian bark is found of the best quality, and in the greatest quantity. Coffee, indigo, sugar, cotton, cacao, ipecacuanha, the tobacco of Varinas, hides, and dried meat, pearls, gold, platina, &c., are obtained in this highly favoured country. Its imports embrace all kinds of manufactured goods, oil, soap, ropes, paper, in fact almost every thing which is wanted by the indolent inhabitants, and made by the hands of men; for the people themselves manufacture hardly any thing. Humboldt has estimated the exports of Colombia at 9,000,000 dollars, and its imports at 11,200,000 dollars. M. Mollien estimates the former at 8,000,000 dollars, and the latter at 10,000,000 dollars. The state of this country, at the present moment, prevents the possibility of obtaining accurate information on this subject. The ports of La Guayra (harbour of Caracas), Rio del Hacha, St. Martha, Carthagena, Chagres, Porto Cabello, Panama, and Guayaquil, are the most frequented by strangers. The English, from Jamaica, the Americans and French, are the nations who trade principally with the Colombians in the Atlantic ports; the Peruvian vessels carry on the coasting trade of the Pacific.

Buenos Ayres, like all the other South American states, is in an unsettled condition. The chief exports of this country are horse and ox hides: in fact, Buenos Ayres may be called, by way of eminence, the country of cattle. Its imports include all the manufactured articles which the inhabitants make use of. England sends thither woollen and cotton cloth, cutlery, hardware, furniture, saddlery, hats, porter, and cheese; the United States, lumber, cod-fish, mackerel and herrings, leather, gunpowder, provisions; from Brazil are sent sugar, coffee, cotton, rum; steel and iron, from the north of Europe; and France sends her manufactures. The exports and imports are estimated at 9,000,000 dollars.

The commerce of *Chili* is, at present, in a low con-

dition. Its rich mines are poorly managed, and the political state of the country prevents its commerce from acquiring that activity which it might easily attain by the export of the precious metals of the country to the East Indies, to give in return for sugar and cotton. It could also provide Peru with salt meat, and take in return coffee, sugar, &c. Caldcleugh estimates the English importations into Valparaiso, in 1822, at 4,071,250 francs, and Lowe at 47,248,625 francs, for the same year. The United States send thither flour.

Peru trades with the United States, with Europe, the Philippine islands, Guatimala and Chili, and by land, with Buenos Ayres. Its exports are chiefly gold and silver, wine, brandy, sugar, pimento, Peruvian bark, salt, vicuna wool, and coarse woollens.—It receives in return, from the United States, breadstuffs and manufactures of various sorts; from Europe, manufactured goods, particularly silks, fine cloth, lace, fine linen, and other articles of luxury und show; from the Philippine islands, muslins, tea, and other East India goods; from Guatimala, indigo; from Chili, wheat and copper; and from Buenos Ayres, mules and Paraguay tea. Calao is the port of Lima.

The commerce of *Central America*, or Guatimala, is increasing in activity. Colonial commodities, chiefly sugar, coffee, cacao, cotton, indigo, cochineal, ebony and logwood (from the bay of Honduras), are the principal exports sent to Europe and some of the United States. The imports are linen, from Germany and France; woollen cloths, silks and wines, from France; English and French calicoes; flour, and some manufactured goods, from the United States. This country is well adapted for commerce, on account of its fine harbours and several navigable rivers. A canal across the isthmus would be of vast benefit to this country; in fact, the execution of such a canal would bear a similarity to some of those great inventions, which have changed the face of the world.

The English, Dutch and French possessions in South America are *Demerara, Berbice, Essequibo, Surinam,* and *Cayenne*. From Cayenne are exported cloves, Cayenne pepper, annotta, sugar, cotton, coffee, and cacao; from Berbice, rum, sugar, cotton, cacao, &c.; from Demerara, Surinam, and Essequibo, sugar, rum, cotton, coffee, and molasses.

West Indies. The chief islands which constitute the West Indies are Cuba, St. Domingo, or Hayti, Jamaica, Barbadoes, Dominica, St. Christopher, or St. Kitt's, Curaçao, and Guadaloupe. They have all very nearly the same productions, viz. sugar, coffee, wax, ginger and other spices, mastich, aloes, vanilla, quassia, manioc, maize, cacao, tobacco, indigo, cotton, molasses, mahogany, long peppers, lignum-vitæ, Campeachy wood, yellow wood, gums, tortoise-shell, rum, pimento, &c. Before St. Domingo or Hayti became an independent government of blacks, it was the depôt of the goods brought from Havannah, Vera Cruz, Guatimala, Carthagena, and Venezuela; but, since that event, Jamaica has been the magazine of all goods from the Gulph of Mexico. Trinidad is the great seat of the contraband trade with Cumana, Barcelona, Margarita, and Guiana. The imports are manufactures of all kinds, wine, flour, and, formerly, slaves, who are still smuggled into many of the islands. The West Indies form one great source of the commerce of the world; and we must refer the reader, for more particular information, to the articles on the different islands.

A new path has been laid open to the commerce of the world by the British, in the Southern ocean, where, of late, the Sandwich, the Friendly, and the Society islands have been taken within the circle of European and American intercourse; and in Australia and Van Diemen's Land, a great market has been established for the exchange of British manufactures for the productions of nature; while the North Americans have attempted to found commercial settlements on the Washington (Nukahiva) and other islands of the Pacific, where they have pursued a system of trade, as honourable and creditable to their merchants, as it will be ultimately beneficial to their country.

Commission. The rule known in commercial arithmetic by the name of commission, is identical with that of brokerage, and reposes on the same principles with interest, discount, insurance, and a variety of other rules, which are usually made the subject of distinct consideration in most of our treatises on arithmetic. It is frequently necessary in mercantile transactions, for one individual to employ another to effect a sale or purchase which he is himself prevented from making. In all commercial communities this employment is generally assigned to a separate class, called brokers, or commission agents, and the remuneration which they receive for their services is termed brokerage, or commission. The amount of this commonly depends on the value of the property bought or sold, for every 100*l.* of which the broker charges a certain sum, determined according to established usuage or special agreement. If this sum be 1*l.* the *rate* of the commission is said to be 1 *per cent.* (per cent. being a contraction of *per centum*, which is the Latin of *for an hundred*); if 2*l.* it is said to be 2 per cent. or 2*l.* for every hundred; if 3*l.* 3 per cent., and if $\frac{1}{2}$*l.* or 10*s.*, it is termed half per cent.

It is very easy to ascertain what is the commission to be paid on any transaction. As the agent is to have a certain sum (according to the rate agreed upon) for every 100*l.* contained in the amount of the sale or purchase he has effected, the whole commission will be that sum taken as many times as there are 100*l.* in that amount. Thus the commisison on 500*l.* at 2 per cent. will be 10*l.*; for there are five *one hundred pounds* in the amount 500*l.*, and $5 \times 2 = 10$. Hence we deduce the following rule:—Divide the amount of the sale or purchase by 100, and multiply the quotient by the rate of the per centage.

Let us take an example, to find the commission on 339*l.* at $2\frac{1}{2}$ per cent.; employing the decimal note line, we have

$$\frac{339}{100} \times 2\tfrac{1}{2} = 3.39 \times 2.5 = 8.475$$

and converting the fractional parts of a pound into shillings and pence, this result becomes 8*l.* 9*s.* 6*d.*

Commodore; a general officer in the British marine, invested with the command of a detachment of ships of war destined for any particular enterprize. He retains this title only during the continuance of the expedition, during which he has the rank of a brigadier-general in the army, and his ship is distinguished from others in his squadron by a broad red pendant. The eldest captain of three or more vessels cruising in company is often c alled *Commodore* by courtesy. In the United States, the title *commodore* is only given by courtesy, not officially.

Commodore Ship, in a fleet of merchantmen, is the convoy and principal ship, which leads the other vessels, and keeps them together, bearing a light in her top.

Company, in military language; a small body of foot or artillery, the number of which varies, but in the English army is generally from 50 to 120, commanded by a captain, a lieutenant, and an ensign, and, sometimes, by a first and second lieutenant, as in the artillery and flank companies of the line.

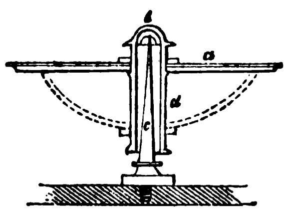
In the Austrian and Prussian armies, companies are stronger. In France, the strength of a company has varied very much. In former times, a company consisted of from 25, 30, 40, up to 200 men; in 1703, of 80 men; in 1808, they had 137 men; in 1814, 72 men; in 1823, 80 men. In 1820, a French battalion was composed of 8 companies, and a regiment of 3 battalions.

Comparative Anatomy is the science which investigates the anatomy of all animals with the view to compare them, to explain one by means of the others, and to classify the various kinds according to their anatomical structure. As comparison, and the formation and extension of genera and species, are the delight of the naturalist, comparative anatomy is one of the most interesting sciences. The want of an organ in certain classes of animals, or its existence under different modifications of form, structure, &c., cannot fail to suggest interesting conclusions concerning the office of the same part in the human subject. Thus comparative anatomy is of the highest importance to physiology. Haller observes, very justly, "Physiology has been more illustrated by comparative anatomy than by the dissection of the human body." Without comparative anatomy, the natural history of animals would always have remained in a backward state, more so even than mineralogy without the aid of chemistry. And it is to comparative anatomy that we owe, in a great measure, that more liberal view of nature which belongs to modern times and considers all nature, man included, as one unbroken whole. See Anatomy and Physiology. The comparative anatomy of the lower orders of the animal kingdom will be fully discussed in our division devoted to Natural History.

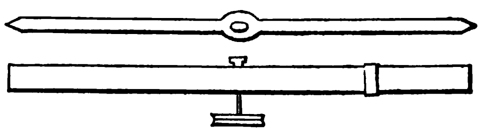
Compass, the Mariner's. The ancients, whose only guides on the trackless waters were the heavenly bodies, so often covered by clouds, could not venture far from shore. It is the compass which has enabled man to steer boldly across the deep. The inventor of this great instrument shares the fate of the authors of many of the noblest inventions. He cannot be precisely ascertained. Some call him Flavio Gioja; others, Giri, a native of Amalfi, in Naples, at the beginning of the 14th century; but there are proofs, that the use of the magnetic needle, in pointing out the north, was known at an earlier period in Europe, and that a contrivance similar to a compass went under the name of *marinette* in France, as early as the 12th century. The English first suspended the compass, so as to enable it to retain always a horizontal position, and the Dutch gave names to the divisions of the card. The earliest missionaries to China found the magnetic needle in use in that country.

The compass is composed essentially of a magnetic needle, suspended freely on a pivot, and containing a card marked with the 32 points of direction into which the horizon is divided, and which are thence called *points of the compass*. The needle always points to the north (excepting slight variations), and the direction which the ship is steering is therefore determined by a mere inspection of the card. This apparatus is enclosed in a brass box, with a glass covering, to allow the card to be seen without being disturbed by the wind. This again is freely suspended within a larger box, so as to prevent, as much as possible, the needle from being affected by the motion of the vessel. The whole is then placed in the binnacle, in sight of the man at the helm. On the inside of that part of the compass-box which is directly on a line with the vessel's bow, is a clear black stroke, called the *lubber-line*, which the steersman uses to keep his required course; that is, he must always keep the point of the card, which indicates his course, coinciding with the lubber-line. The compass here described is called the *steering compass*.

We have now to notice an improvement on the common compass. In high northern and southern latitudes, the opposite ends of the needle dip to so great an extent as to preclude the motion of the instrument. To prevent this inconvenience, a compass has lately been constructed which allows the needle *a*, to dip without destroying the equilibrium of the card to which it is attached. The curve described by the extemity of the needle, is shown by the dotted line *d*,



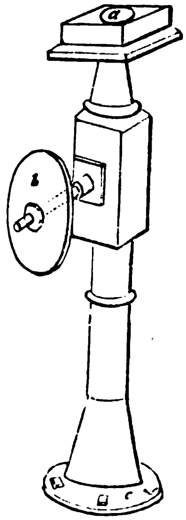
the card retaining its horizontal position, whilst the cap *b*, remains equally balanced on the point *c*.—To effect this, the compass bar, or needle, is suspended by a joint, consisting of two small pivots resting in a frame. The cause of the "dip," to which we have alluded, will be explained under the article Dipping Needle. In the compasses for use on land, a similar effect is produced by a small sliding weight placed on the needle.—Its situation is shown in the bar baneath.



The two views are intended to exhibit the proper relative proportion of the sides of the bar. If the bar was square, less effect would be produced with a given weight of metal than where this form is adopted.

In all vessels, and especially in those which have large masses of iron on board, the effect of the metal tends most materially to impair the accuracy of the compass, and, in some cases, to cause the loss of vessels at sea; and we shall now briefly notice Mr. Barlow's admirable discovery of a method of counteracting the local attraction of vessels. For this discovery, Mr. Barlow received the highest reward, viz. that of £500, given by the Board of Longitude. The instrument, as constructed by Mr. Barlow, is thus described: The centre of a small circular plate

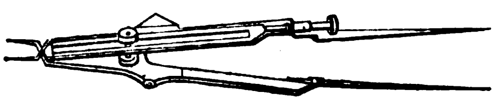
of iron, shown at *b* is placed in the line of the attraction of the ship's iron, and at a proper distance behind and below the pivot of the compass-needle, *a*; the position of this line having been previously ascertained, an operation now rendered easy by the tables for this purpose prepared by Mr. Barlow, and given with the instrumemt. When this is done, the needle will remain in operation in the polar regions, and direct itself in the true magnetic meridian, in whatever part of the world the ship may be. This effect of Mr. Barlow's invention has been established by experiments, between the 61° of south latitude, and the 81° of north latitude, by the accurate observations of Lieutenant Foster, and other naval officers.



With respect to the plate itself, it has hitherto been made double, viz. of two plates screwed together, in such a manner as to combine any strong irregular power of the one with a like weak point in the other; by which means a more uniform attraction is obtained. The plates may vary from 12 to 16 inches in diameter, according to the power of the vessel. They have a hole in their centre, through which is passed a brass socket, with a broad head, and with an exterior screw or nut, by which the two plates and an interposed piece of wood of the same size are compressed strongly together, the board being intended to increase the thickness, without adding much to the weight; and it is found that the two plates thus separated are more powerful than when in contact.

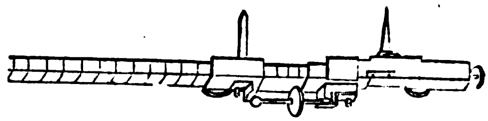
Compasses, or Pair of Compasses; a mathematical instrument, used for the describing of circles, measuring lines, &c. The common compasses consist of two branches, or legs of iron, brass, or other metal, pointed at bottom, and joined by a rivet, whereon they move as on a centre. We have compasses of various kinds and contrivances, accommodated to the various uses for which they are intended.

The only two forms which require a particular notice are the *proportional* and *beam* compasses. The first of these is represented beneath.



They consist of two limbs jointed in some point intermediate between either extremity. If in the centre, then the two extreme ends will describe circles of the same diameter; but if at one-fourth from one end, then a drawing may be reduced to one-third of its original dimensions, or *vice versá*. We exhibit an instrument thus constructed in the figure, but it possesses a species of delicate adjustment in the screw passing parallel to the upper limb, which enables the artist to make minute alterations in the general proportions of the figure. This he may effect by turning the screw and slightly changing the comparative length of the limbs. It may be proper to add, that the power of the instrument is considerably increased by cutting a groove in both limbs.

The beam compass consists of a bar with two points, one of which is fixed and the other moveable; and it will be found, on inspecting the annexed figure, that it is in its operation precisely similar to the common compass, but used in a horizontal position, which admits of a greater span or opening between the two points. The moveable point contains the pencil, and, in the best instruments, it is provided with an adjustment, as shown beneath.



Complement, Arithmetical. We observed, under the head of *subtraction*, in the article Arithmetic, that there was a mode of subtracting numbers by means of what is termed their arithmetical complement, which was attended in peculiar cases with considerable advantage; we will now explain it. Suppose that we have to subtract 614 from 5347, that is, to find the difference of 5347—614 This difference will not be effected by adding any number to it, provided that at the same time we subtract the same number from it. Let this number be 1000; then 5347—614 is the same as 5347 + (1000—614)—1000, or as 5347 + 386—1000. Now, instead of 386—1000, let us write $\bar{1}386$, incorporating 1000 with 386, but at the same time marking that it is subtracted, by putting the negative sign over it, so that 5347—$\bar{1}386$, has the same meaning as 5347 + 386—1000; $\bar{1}386$ is termed the arithmetical complement of 614. Similarly, the arithmetical complement of 1614 is $\bar{1}8386$, or of 252, $\bar{1}748$ or (1000—252)—1000, and that of 84, $\bar{1}16$ or (100—84)—100.

As we can perform such a subtraction as 614 from 1000 mentally, and obtain the result almost as soon as we could write down 614 itself, the advantage of employing these complements is considerable, where we have to find the result of several additions and subtractions, such as 5347—1614 + 18342—252 + 640—84; for by their use we get rid of every subtraction (with the exception of the very easy one of each 1000), and have only to perform an operation of addition. Taking the arithmetical complement of each of the numbers to which the negative sign is prefixed, we have

$$\begin{array}{r} 5347 \\ \bar{1}8386 \\ 18342 \\ \bar{1}748 \\ 640 \\ \bar{1}16 \\ \hline 22379 \end{array}$$

This method is much more expeditious than the ordinary one of taking separately the sum of the positive and of the negative terms, and then finding the difference of those sums.

Composite Order. See Architecture.

Compost, in *husbandry* and *gardening;* several sorts of soils, or kinds of earthy matter mixed together; or a mixture of earth and putrid animal substance; in fact, any artificial manure to assist vegetation.

Compound Numbers. By means of one unit, and its fractional parts, we are perfectly capable of expressing accurately the magnitude or *size* of any thing. If the only unit of distance we employed were a very small one—for instance, that known by the name of an *inch*—we should still be at no loss to denote the magnitude of any body, however great, by simply stating how many inches it contained. Instead of 1 *mile*, we should say 63360 inches; instead of 1 *yard*, 36 inches; and instead of 1 *foot*, 12 inches. Again, were our sole unit a great one—a mile for example—it would still suffice for all purposes connected with the measurement of length; 1 yard, 1 foot, and 1 inch would be just as precisely described by the $\frac{1}{1760}$th, $\frac{1}{5280}$th, and $\frac{1}{63360}$th of a mile respectively. But either of these methods would be attended with great inconvenience; in the one case it would be necessary to employ very large numbers, in the other our operations would be greatly encumbered with fractions. Hence it is customary in all civilized communities to have for each kind of thing a scale of units of different magnitudes or *denominations*, as pounds, shillings, pence, and farthings, for units of value, in England; miles, furlongs, poles, fathoms, yards, feet, and inches, for units of length; seconds, minutes, hours, days, &c., for units of time, and so on. A quantity expressed in units of different denominations is called a *compound number*.

It is evident that numbers may easily be changed from one denomination into any other of the same kind; the rules by which this change is effected are those of *Reduction*. Particular rules are also requisite for the addition, subtraction, multiplication, and division of compound numbers; these we shall now state.

To add compound numbers together, the common rule is: write them under one another, the numbers of the same denominations being all in the same column; add together those composing the column of the lowest denomination, and reduce it as far as practicable into the next higher; write under the column of the lowest denomination the part of its sum that remains of that denomination after the operation of reduction has been performed, and carry the other part to the next column; proceed through all the other columns in the same manner.

For example, the sum of 1*l.* 16*s.* 9*d.*, and 4*l.* 7*s.* 6*d.* must evidently be 1*l.* + 4*l.* 16*s.* + 7*s.* and 9*d.* + 6*d.*, or 5*l.* 23*s.* 15*d.*; but 15*d.* is equal to 1*s.* 3*d.*, and 23*s.* is equal to 1*l.* 3*s.*; therefore the sum becomes 5*l.* + 1*l.* 3*s.* + 1*s.* and 3*d.*, or 6*l.* 4*s.* 3*d.*

The rule for the subtraction of one compound number from another is this: write the number to be subtracted under the other, as in addition. When a number of any denomination in the upper number is less than the corresponding one in the lower, add to it as many units of that denomination as will make one unit of the next higher denomination, taking care at the same time always to increase the number of the next higher denomination in the lower number, by unity; then subtract the number of each denomination in the lower number from the number of the corresponding denomination in the upper.

Let us take for an example, to find the difference between 7*l.* 7*s.* 3*d.* and 4*l.* 18*s.* 6*d.* Here, as the number of the denomination of pence in the minuend (the upper number of the rule) is less than the number of the same denomination in the subtrahend (or lower number of the rule), we add to it as many units of that denomination (which is that of pence), as are equal to one unit of the next higher denomination (or that of shillings), namely 12; at the same time adding to the number of the next higher denomination in the subtrahend 1*s.*, which is equivalent to the 12*d.* we have given to the minuend. The pence number of the minuend thus becomes 15, and greater than the pence number of the subtrahend; and the shillings' number of this latter, 18, becomes by the addition of the 1*s.*, 19; this again being greater than 7, the shillings' number of the minuend, we increase this smaller one by 20—the number of units of the denomination of shillings necessary to make one unit of the next higher denomination, or that of pounds, taking care also to add one of these equivalent units to the 4*l.* of the subtrahend, thus to make it 5*l.* The difference required will then be 7*l.* − 5*l.* 27*s.* — 19*s.* 15*d.* — 6*d.*; or 2*l.* 8*s.* 9*d.*

To multiply a compound by a simple number, the ordinary rule is this:—multiply the number of every denomination in it by the simple number, and reduce each result to the highest denomination to which it is susceptible of reduction. There is, however, a much better way of performing this operation by means of the rules of *Practice*.

To divide a compound number by a simple number: Divide the number of the highest denomination by the divisor, and write the whole part of the quotient as the number of that denomination in the general required quotient; reduce the remainder, if any, to the next lower denomination, and adding it to the number of that denomination in the dividend, proceed as before, continuing this mode of operation till the number of every denomination has been divided; the several partial quotients obtained, form the numbers of the different denominations of the general quotient.

It is unnecessary to say any thing on the last two rules, as, together with the first two we have already spoken of, they are founded on the same principles as the similar operation, or simple numbers, which we have fully developed in the article **Arithmetic**. The multiplication and division of one compound number by another, will come more properly under the head of **Practice**.

Compressibility; the quality of bodies of being reducible, by sufficient power, to a narrower space, in consequence of their porosity, without diminishing their quantity of matter. All bodies are probably compressible, though the liquids, in particular, offer an almost invincible resistance to compression. Those bodies which occupy their former space when the pressure is removed, are called *elastic*.

Compression Machines; instruments for compressing or condensing elastic fluids. Such, for instance, is an air-pump with cocks, by which the air can be condensed in tight vessels. For the compression of liquids a very ingenious experimentor has constructed a metallic cylinder of 21 inches $5\frac{10}{12}$ lines high, and $3\frac{1}{2}$ inches $7\frac{1}{2}$ lines in diameter, 1 inch $2\frac{1}{2}$ lines thick. This cylinder is filled with water, and an iron piston, covered with leather, and exactly fitting the bore, is pressed into it. For this pressure, a screw was first used; but, in order to produce a better application of the power, a lever was afterwards employed to force down the piston. A mark on the piston shows, by its distance from a little ledge across the cylinder, how far the piston

has been forced down, and, when the force subsides, how far it has been driven up. See CONDENSATION.

CONCAVE; hollow; the reverse of convex.

CONCAVE LENS; an epithet for glasses ground hollow on the inside, so as to refract the rays of light.

CONCAVE MIRRORS. See OPTICS.

CONCENTRATION, in *chemistry;* the act of increasing the strength of fluids, by volatilizing part of their water.

CONCENTRIC; an epithet for figures having one common centre.

CONCERT; a musical performance, in which any number of practical musicians, either vocal or instrumental, or both, unite in the exercise of their respective talents. The concerts of the ancient Greeks were executed only in the unison or octave.

CONCERTO; a kind of musical composition, which is an imitation of the solo song with accompaniments—in short, an imitation of the *aria*. In the concerto, one chief instrument is distinguished, and leads the rest. In the case of such concertos, the performance is called after this instrument, or it is called, in general, *concerto di camera*. The term *double concerto* is used if there are two chief instruments.

Concerto Grosso is an expression applied to the great or grand chorus of the concert, or to those places of the concert in which the *ripienos* and every auxiliary instrument are brought into action, for the sake of contrast and to increase the effect.

Concerto Spirituale was a concert at Paris, performed in the religious seasons, when the theatres were closed. The pieces performed, however, were not always of a spiritual kind. It was introduced in 1725, by Anne Danican, called *Philidor*.

CONCHA AURIS, in *anatomy;* the large hollow of the external ear.

CONCORD; an expression used in music. It denotes an association of sounds, founded on the natural relations of simultaneous tones. Upon this association depends all harmony; in fact, every proper chord is of itself harmony; hence, the expression *harmony of the dominant*. In its proper acceptation, harmony is the result of connected tones in consecutive chords.

With regard to their simultaneous expression, however, tones differ in their relations. Some, by the mere act of being sounded together, convey to the ear a sense of pleasure. They harmonize in themselves, and are therefore termed *consonant chords*, or *concords*. Take, for example, one tone as the fundamental tone; then, to form a concord, all the other tones must harmonize with it and with each other. The idea of a chord has no reference to the number of consonant tones of which it is formed. The most simple and least perfect concord is made by the combination of two tones, and is formed by connecting the interval of the third with the fundamental tone. The most perfect consonant chord is the harmonic triachord, which is formed by the addition of another third, and constitutes the perfect fifth from the fundamental tone; it is usually termed the *dominant*.

From the character of the first third, or mediant, these combinations are either major or minor; thus, major C, E, G, or minor C, E flat, and G. The minor triachord is to be distinguished from the diminished triachord, which by some is called the *false* or *dissonant*, and is formed by two minor thirds, or by the fundamental tone and the minor third and minor fifth; thus C, E flat, G flat. There is also a redundant triachord, constituted by two major thirds. By the transposition of the tones composing these triachords into higher or lower octaves (changing the positions or inverting the intervals), all other consonant chords are formed. It is usual to fix the designation of chords by counting the intervals ascending. Thus arises, first, the chord of the sixth (hexachord), in which the fundamental tone is placed an octave higher, so that the third becomes a fundamental tone; the fifth is then the third, and the transposed fundamental becomes the sixth; thus, E, G, C, designated by the figure 6. Second; the chord of the fourth and sixth, where the fundamental tone and its third are both placed in a higher octave, so that the fifth becomes the fundamental, the original fundamental is changed to the fourth, and the transposed third becomes the sixth. Hence the name, from the characteristic intervals and the notation, thus, $\frac{6}{4}$. The dissonant chords are first obtained by adding to the triad another third, which, consequently, stands in the relation of a seventh to the fundamental, and produces a quadrichord. The seventh is the dissonant interval, and, to relieve the ear, requires to be resolved. The chord of the seventh is formed of the fundamental, the third, the fifth, and the seventh. The first, and most usual, is constituted by the major triad with the minor seventh; thus C, E, G, B flat. It is called the *principal*, sometimes the *essential chord of the seventh*, and is simply designated thus, 7. It rests upon the dominant of that key in which it is to be resolved; for the minor seventh resolves itself downwards, thus, , while the major dissonant ascends. Hence it may also be called the *dominant chord of the seventh*, or the *chord of the dominant seventh*. If we transpose the intervals of these chords, in the same manner as with the triachords, we form, first, the chord of the fifth and sixth (denoted by $\frac{6}{5}$), consisting of the minor third, the minor fifth and major sixth, thus, ; Second; the chord of the third and fourth $\left(\frac{4}{3}\right)$, in which the seventh and the fundamental tone of the essential chord of the seventh become the third and fourth, ; Third, by farther transposition, the chord of the second is formed, by which the seventh, with the fundamental tone, forms the interval of the second, thus, . The

other chords of the seventh, which Weber terms *by-chords of the seventh*, in opposition to *principal chords of the seventh*, are, the chord of the seventh, formed by the minor triachord and the minor seventh, ; again, by the diminished triachord, with the subsisting minor seventh of the chord of the seventh, ; finally, the chord of the seventh, with the major triachord and seventh major, . By the transposition of these by-chords of the seventh are formed the chords of the fifth and sixth, the third and fourth, and the chord of the second.

We have thus, as appears from this review, nine fundamental chords, viz. two simple accords, three triachords, and four chords of the seventh (the essential chord and the by-chords of the seventh). However complicated the harmony may be, it is reducible to these chords. There is yet a five-toned chord, the *quint-chord*, which is a union of simultaneous tones, and is formed by the addition of another third (major or minor) to the chord of the seventh, which consequently makes the ninth from the fundamental tone, and is termed the *chord of the ninth*. But if, from the adverse concurrence of the seconds, we omit the fundamental tone, as is usual in close harmony, and transpose the notes as above, we obtain thus the proper modifications of the quadrichord; for example, the enharmonic chord of C, E flat, G flat, A; C sharp, E, G, B. These concords, then, are capable of being presented in the most diversified forms—in immediate collision, or broken, so that the tones constituting them are heard in succession. Farther, the intervals may be confined to one octave, or distributed through distant and different octaves. This forms the ground-work and the distinction between close and dispersed harmony, according to the close or dispersed position of the chords. Farther, the application of the intervals composing the chords is governed by the variety of positions, inasmuch as the music may be adapted for two, three, four, five voices or parts. In the former, some intervals must be omitted; in the latter, doubled.

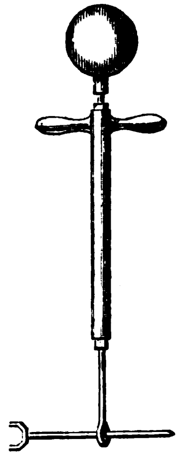
One of the first systems of chords was offered by Rameau, grounded on the ideas of D'Alembert, and afterwards elucidated in Marpurg's system, which much resembled Vogler's. It has been more recently elucidated by Türk. Another is by Tartini, which is given in Rosseau's *Dictionaire de la Musique*. The one deduces and explains the chords from fundamental keys (of the bass), the other from melody (the upper tones). Another very simple system of chords is that of Kirnberger, which is much followed by Godfrey Weber, in his treatise on thorough-bass.

From music, the idea of harmony is transferred to colours, and we may speak of the *harmony* of colours, as opposed to the harsh and dazzling contrast of them, which is avoided by a judicious middle tone of colouring.

Concretions, Morbid, in *animal economy;* hard substances that occasionally make their appearance in different parts of the body, as well in the solids as in those cavities destined to contain fluids: in the former case, they are denominated *concretions* or *ossifications;* in the latter, *calculi*. The concretions that make their appearance in the solids of the animal body are denominated *pineal* concretions, from their being found in that part of the brain called the *pineal gland;* or *salivary* concretions, as being discovered, occasionally, in the salivary glands; or *pancreatic* concretions, which are hard substances found in the pancreas; or *pulmonary* concretions, which have been sometimes coughed up by consumptive persons; or *hepatic* concretions, of which the liver is sometimes full. Concretions have also been found in the *prostate*. These have all been examined by chemists, and found to consist of phosphate of lime and other substances. Concretions have been discovered in the intestines and stomach of man, but more frequently in the bodies of other animals. Those found in the intestines of a horse were examined by Fourcroy, and found to consist of magnesia, phosphoric acid, ammonia, water, and animal matter.

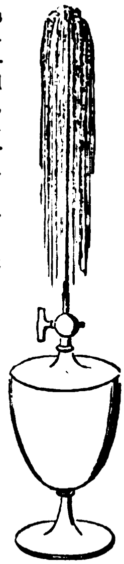
Condensation; the act of diminishing the bulk of a body.—Thus steam is condensed into water, by abstracting its heat, by which it is reduced in volume about two thousand times. By similar means gases are converted into fluids, and the latter into solids; but the most important species of condensation is that by mechanical means, which we may now proceed to describe.

It has already been shown, under the article Air, that the fluid atmosphere which surrounds our globe, is elastic, that its bulk may be reduced by mechanical means, and that this elastic force can, under certain circumstances, be employed as a substitute for gunpowder. The mode of accomplishing this, will be better understood by referring to the accompanying engraving.

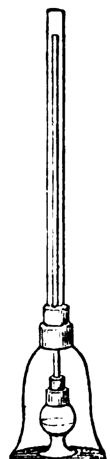


The syringe is furnished with a piston, made to fit air-tight, and provided with a strong metal ball, which may be attached or withdrawn at pleasure. If we now suppose the apparatus arranged as shown in the figure, and the piston depressed, it will be obvious that as much air as was previously contained within the tube, must be forced into the ball, where it is retained by a spring valve opening inwards. There is a very curious phenomenon which may be illustrated by this apparatus. What we call *dry air* would at least appear free from any considerable quantity of water. Such, however, is not the fact, as the warm air of a room in the summer season, will produce a complete shower of fine rain-like particles. To perform this experiment, the valve of the ball should be opened suddenly, when the air is in its highest state of condensation, and the water may then be received either on paper or a metal plate.

We may readily convert this species of condenser into a portable air-fountain, of which we give a diagram.—The syringe is, in this case, screwed on the upper end of the stop-cock, which is provided with a pipe descending beneath the surface of the water within. If we now suppose the air injected, and the syringe withdrawn, on opening the stop-cock, a jet of water will be impelled from the orifice, and in many cases raised ten or twenty feet in height. This pretty philosophical toy serves to illustrate the use of the air-condenser in a fire-eninge. It will be obvious that the power of those who are employed to work the engine, is imparted by a series of jerks, and yet the water passes from the ajutage in one continued flow. Now this practical advantage results from the use of a quantity of air, imprisoned within the condenser, which by its elasticity prevents the destruction of the pumps, and, at the same time equalises the motion of the stream of water.



We have now to examine the apparatus which is used for ascertaining with mathematical accuracy the precise amount of compression of any given volume of air. The apparatus consists of a tall glass tube closed at the top, and dipping in a vessel of mercury. This is placed beneath a receiver, firmly attached to a condensing plate; and on injecting air by the syringe, it presses on the surface of the mercury, driving it up the tube, If we find it ascend about half-way up the tube, then it is said to contain two atmospheres. The receiver, with tube, is shown in the diagram.



The common condensing-guage consists of a short tube, which is screwed to the receiver, and furnished with a graduated plate, by which the amount of compression is indicated.

CONDUCTOR. See ELECTRICITY and LIGHTNING.

CONDUIT, in *architecture;* a long, narrow passage between two walls, or under ground, for secret communication between various apartments, of which many are to be found in old buildings; also a canal of pipes, for the conveyance of water; a sort of subterraneous or concealed aqueduct. The construction of conduits requires science and care. The ancient Romans excelled in them, and formed the lower parts, whereon the water ran, with cement of such an excellent quality, that it has become as hard as the stone itself, which it was employed to join. There are conduits of Roman aqueducts still remaining, of from five to six feet in height, and three feet in width.—Conduits in modern times, are generally pipes of wood, lead, iron, or pottery, for conveying the water from the main spring or reservoirs to the different houses, and places where it is required. (See AQUEDUCT.)

CONE, in *geometry;* a solid figure, having a circle for its base, and its top terminated in a point or *vertex*. This definition, which is commonly given, is not, in mathematical strictness, correct; because no circle, however small, can become a mathematical point. But these deficiencies of mathematical strictness connected with constructive geometry, which is based on figures and diagrams, are avoided by analytical geometry, which operates without figures.

The word *cone* is derived from the Latin *conus.*—The figure might be called the *round pyramid,* according to the definition of a pyramid. Cones are either *perpendicular,* if the axis, that is, the line from the vertex to the centre of the base, stands perpendicularly on the base; or *oblique,* or *scalenous,* if the axis does not form a right angle with the base. If a cone is cut parallel with its base, the section, of course, is a *circle:* if, however, the section is made obliquely, that is, nearer to the base at one end than at the other, a curve is obtained, which is called an *ellipse*.

If the section be made parallel with the axis, perpendicularly from the vertex, or so as to make a greater angle with the base than is made by the side of the cone, the curve obtained is called a *hyperbola*. Thirdly, the section may be made parallel with one side of the cone, in which case the curve is called a *parabola*. These three lines, figures, and planes are called *conic sections,* and form one of the most important parts of mathematics, which is distinguished for elegance, demonstrating, with surprising simplicity, and beauty, and in the most harmonious connection, the different laws, according to which the Creator has made worlds to revolve, and the light to be received, and reflected, as well as the ball thrown into the air by the playful boy, to describe its line, until it falls again to the earth. Few branches of mathematics delight a youthful mind so much as conic sections; and the emotion which the pupil manifests, when they unfold to him the great laws of the universe, might be called natural piety.

Considering conic sections as opening the mind to the true grandeur and beauty of the mathematical world, whilst all the preceding study only teaches the alphabet of the science, we are of opinion that the study of them might be advantageously extended beyond the walls of colleges, into the higher seminaries for the education of females. The Greeks investigated the properties of the conic sections with admirable acuteness. A work on them is still extant, by Apollonius of Pergarnus. (See SECTIONS, CONIC.)

CONGELATION, *limit of perpetual.* Under COLD and TEMPERATURE our readers will find the phenomena of freezing and the effects of cold fully illustrated; but as all great mountain ranges have a point usually termed the "limit of perpetual congelation," it may be proper to notice the subject in a distinct form. We may suppose a traveller ascending Chimborazzo; he will, at the base, find a burnt and arid plain, and as he ascends the mountain, this will gradually give place to the trees and flowers of a more genial clime. Still higher, the Alpine, or severe mountain scenery will be observable, and after passing the lichens and more hardy plants, there will be a tolerably well defined climate of perpetual winter. Here, the snows are eternal as the mountains on which they fall, and seem distinctly to mark the barrier to which the labours of man and the progress of civilization shall be confined.

The limit of perpetual congelation in the Hymalaya Mountains, has been a matter of some controversy. A learned writer in the *Quarterly Review* has asserted, that this height is below 11,000 feet above the sea, and has maintained that the height of the range

itself, will be found much inferior to that of the Andes. Captain Webb, from numerous heights taken with the barometer, has drawn a very different conclusion.

"Near the temple of Milum (says Mr. Fraser, in his work on the great Himalaya Mountains), elevated 11,405 feet, there were large fields of good rye, and buck-wheat, and at an elevation of about 13,000 feet, he procured some plants of spikenard. On the 21st of June, Capt. Webb's camp was 11,680 feet above Calcutta. The surface was covered with rich vegetation as high as the knee, very extensive beds of strawberries in full flower, and plenty of currant-bushes in blossom all round, in a clear spot of rich black mould soil, surrounded by a noble forest of pine, oak, and rhododendron. And on the 22d of June, he reached the top of Pilgoenta-Churhaee, 12,642 feet above Calcutta.—There was not the smallest patch of snow near him, and the surface was covered with strawberry plants, butter-cups, dandelion, and a profusion of other flowers. The shoulders of the hill above him, about 450 feet more elevated, were covered with the same to the top, and about 500 feet below was a forest of pine, rhododendron, and birch." These facts led Captain Webb to infer that the inferior limit of perpetual congelation in the Himalaya Mountains, is beyond 13,500 feet at least above the level of Calcutta.

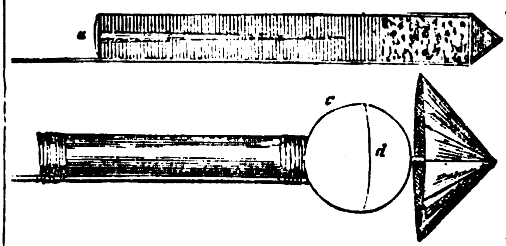
Congestion; a diseased state of the human structure, arising from an accumulation of the blood. The different parts of the human body do not always receive the same quantity of blood, but sometimes more, sometimes less. Thus, for instance, during digestion, it flows towards the stomach and the liver; during violent or long-continued speaking, singing, or running, it collects in the lungs and the heart; during close thinking, in the brain.

In general, the blood flows in greater quantities into any part in proportion to the action of that part; but, in a state of health, it flows off with as much rapidity as it collects. Sometimes, however, too much blood accumulates in an organ, and remains too long in it; and this injures the structure and the function of such an organ. Congestion may be caused by whatever, in general, accelerates the circulation of the blood, and causes it to tend to a particular part; thus, for instance, among the causes of congestion are the different periods of developement of the human body, each of which renders some particular organ unusually active; the crisis of disease; and, lastly, the accidental exertions of certain organs.

Under such circumstances, congestion is caused by an excited state of the arteries in general, and of some particular ones especially. Secondly, if the current of blood to one organ is checked, it accumulates in another. Hence, colds caught through exposure of the feet, also the suppression of the secretions, &c., so often cause congestion. Thirdly, the vessels which bring back the blood—the veins—are sometimes in a condition unfit to answer their destination; as for instance, if they are already too full, if their power to receive the blood and to propel it is lost or diminished, or if they are prevented from performing their function by external pressure, or by tumours. Hence congestions are divided into active and passive; those of the arteries and those of the veins. Where the blood accumulates, the part becomes red and hot, the pulse beats more violently, and the veins expand; the part swells, and a feeling of sickness, pain, pressure, &c. comes on. The functions of the part change; if the congestion is slight, they become more active. In higher degrees of congestion, and if it is continued for a long time, the functions are checked, weakened, and sometimes entirely destroyed.

Now, as every organ has its peculiar function, it follows, that the symptoms of congestion, resting on these grounds, must be very different, according to the different organs in which it takes place. During the congestion of blood in one organ, the other organs exhibit symptoms of want of blood, viz. coldness, paleness, diminution of size, and weakness. Congestion generally lasts but a short time; but if not early cured, and its return, which would otherwise be frequent, prevented, it is only the beginning of other diseases. Sometimes it terminates in bleeding, which is a remedy for it; sometimes it increases into inflammation; sometimes it becomes a chronic disease; that is, the blood accumulates for a long time, and expands the veins; the expansion becomes permanent, and the original excitement is succeeded by a state of torpidity and weakness, which is called *stagnatio*.

Congreve Rocket. This terrific weapon of destruction is, as its name implies, the invention of the late Colonel Congreve. Its two principal forms are represented in the engraving.



The simplest form of the rocket is delineated at *a*, *b*; the principle on which it ascends will easily be understood. If we suppose a tube filled with any inflammable material, ignited at an opening in the end, *a*, the disposition to expand will be equal in every direction: but as the resistance of the case is taken away at the opening, *a*, it will, of course, have a disposition to ascend in the opposite direction. The case, which is of copper or iron, and its destructive contents, are thus impelled with resistless force against the hostile ranks of an army, or the walls of a fortress.

The Congreve rocket has lately been enlisted in the cause of humanity, by the instantaneous destruction of large animals. We have been informed by a whale-fisher of much experience, that this species of missile is, in most cases, infinitely superior to the harpoon; and if, for argument sake, we admit the propriety of destroying those large and inoffensive "monsters of the deep," we should, at least in their deaths, remember mercy.

To the ball rocket, *c*, *d*, a parachute is attached, by which the rocket is partially supported in the air; and there are cases in which an instrument of this kind becomes exceedingly valuable for illuminating the neighbourhood of a fortress or out-work, during a night attack.

Conservatory; a musical school intended for the scientific cultivation of musical talents. They are sometimes public benevolent establishments, including hospitals, supported by rich private persons.—

The pupils have board, lodging, clothing, and instruction gratis. Besides these pupils, others are received who pay for their instruction; as, in Italy, the instruction in conservatories is preferred to private teaching. In Naples there were formerly three conservatories for boys; in Venice, four for girls. The most famous among the former was that of Santa Maria Loretto, established in 1537. Leo, Durante, Scarlatti, and Porpora were teachers at this school; and, among the great musicians educated there, it counted the distinguished names of Traetta, Piccini, Sacchini, Guglielmi, Anfossi, Paesiello, and others.

There were generally more than 200 pupils from eight to ten years of age in the conservatory of Loretto; in the others, about half this number. Pupils were received from eight to twenty years of age. The period during which they obliged themselves to stay in the establishment was generally eight years. If, however, it was discovered that a pupil had no talents for music, he was sent away. The conservatories in Venice were established in the same way. They were called *ospedale della pietà, delle mendicanti, delle incurabili,* and *ospedaletto di San Giovanni e Paolo.* Sacchini was for a long time the first instructor in the latter. The girls were obliged to conform to a very strict monastic kind of life, and used to remain in the establishment till they were married.

All instruments used in the public concerts were played here by girls and women. From these conservatories issued the great number of composers and male and female singers, who were met in every part of Europe. In Naples, the conservatories are reduced to a single establishment, which, in 1818, was removed to the former nunnery of St. Sebastiano, and received the name *real Collegio di Musica.* In Milan, the viceroy Eugene established a conservatory in 1808, the direction of which was given to Asioli.—It has 14 professors and 60 pupils.

In France, music was very little cultivated until Italian and German music was introduced by Piccini, Sacchini, Gluck, and others. The want of singers was now felt. The opera therefore established a musical school, and, in 1784, it was elevated into an *école royale de chant et de déclamation.* But it was not until the revolution that this institution acquired a high degree of importance. The want of musicians for fourteen armies was then felt, and in 1793, the Convention decreed an *institut national de musique.*

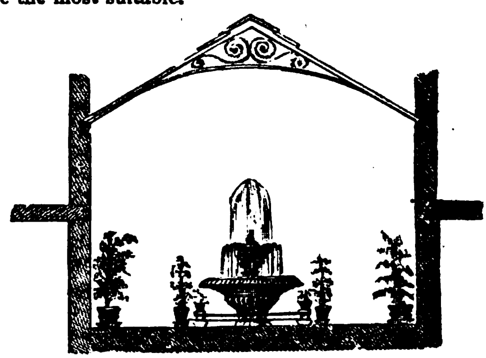
In 1795 it received its final organization, and the name of *conservatoire.* It was intended for both sexes. 600 pupils, from all the departments, were to be instructed there by 115 teachers. The expenses were fixed at 240,000 francs annually, but, in 1802, were limited to 100,000 francs, and, in consequence, the number of pupils and teachers was reduced.

The instruction was divided between music and theatrical declamation. The most distinguished musicians have been instructors in this institution; of whom we need only mention Gossec, Méhul, Garat, Choron, Cherubini, Grétry, Boïeldieu, Kreutzer, &c. Since its foundation, 2,000 musicians and singers of both sexes have been educated there. At the same time, the *conservatoire* is the central point of all amateurs of music. The public performances of the pupils are the most splendid concerts in Paris. The execution of symphonies, in particular, is unparalleled. For almost all branches of music, the *conservatoire* has published elementary works, or *methods,* as they are called, which are circulated, and adopted throughout Europe. Our own Royal Academy of Music is an establishment of a similar character.

Conservatoire Royal des Arts et Métiers, at Paris, is an establishment, which deserves the greatest praise, containing a collection of models of machines, of manufactures, &c., and having professors, who deliver lectures on mechanics, chemistry, and the processes used in manufacturing, to persons who wish to prepare themselves for pursuing mechanical arts, and the business of manufacturing in a scientific way. The foundation of this praiseworthy establishment was laid Oct. 10, 1794. After many important changes, is was finally organized by an ordnance, Nov. 25, 1819. There is now a valuable institution established in our metropolis for the exhibition of the useful arts. It is situate in Adelaide Street.

CONSERVATORY, in *gardening,* is a term generally applied, by gardeners, to plant-houses. They are sometimes placed in the pleasure ground, along with the other hot-houses, but more frequently attached to the mansion. The principles of their construction are in all respects the same as for the green-house, though, occasionally, a pit, or bed of earth is substituted for the stage, and a narrow border instead of surrounding flues. The power of admitting abundance of air, both by the sides and roof, is highly requisite, both for the green-house, and conservatory; but for the latter, it is desirable, in almost every case, that the roof, and even the glazed sides, should be removeable in summer.

When the construction of the conservatory does not admit of this, the plants in a few years become etiolated and naked below, and are no longer objects of beauty; but when the whole superstructure, excepting the north side, is removed during summer, the influence of the rains, winds, dews, and the direct rays of the sun, produces a bushiness of form, closeness of foliage, and a vividness of colour, not attainable by any other means. Therefore a conservatory, of any of the common forms, unless it be one devoted entirely to palms, ferns, *scitamineæ,* or other similarly growing plants, should always be so constructed as to admit of taking off the sashes of the roof and the front; and if it be a detatched structure in the flower-garden, a plan that would admit of the removal of every thing excepting the flues and the plants, would be the most suitable.

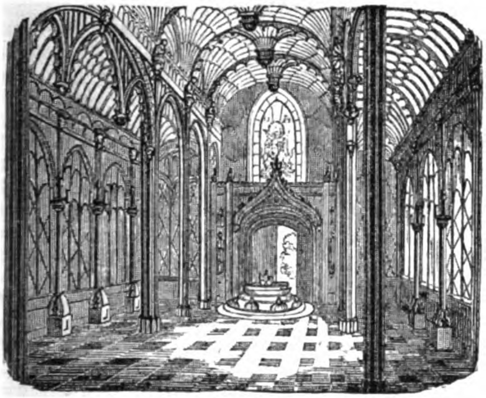


A conservatory well fitted for ornamental as well as practical purposes, is represented above, and it superadds the advantage of a fountain, which is at all times a considerable addition to edifices of this description,

Mr. Bailey, of Holborn, erected a very beautiful

domed conservatory, for the late Mrs. Beaumont, but, strange to relate, her son has since sold the entire edifice, one of the finest in the world, for little more than the worth of the materials.

One of the most beautiful Gothic conservatories yet constructed, was designed by the late Mr. Wyatt, for Carlton Palace, of which it formed a part. It was occasionally dismantled of its trees, and, in this state we present it to our readers, in the subjoined engraving.



Conserve, in *pharmacy*, &c.; a form of medicine or food, contrived to preserve the flowers, leaves, roots, peels, &c. of several simples, as near as possible to what they were when fresh gathered, to give them an agreeable taste Conserves are prepared from recent vegetable matter beaten together with sugar into an uniform mass. Vegetables, which soon lose their virtues by drying, may be preserved by this process, unimpaired, for a considerable length of time, the sugar preventing the natural decomposition, and moulding, which would otherwise take place. The sugar is first ground to a fine powder, and then mixed by long beating (not by solution) with the vegetable pulp or other material. No heat or other mode is employed, so that the vegetable matter remains, as nearly as possible, in the state in which it existed in the plant, at the moment of gathering.

Constellations are the groups into which astronomers have divided the fixed stars, and which have received names for the convenience of description and reference. The science of the constellations is called *astrognosy*.

The division of the stars into groups was begun in ancient times. It is plain that the union of several stars into a constellation, to which the name of some animal, person, or inanimate object is given, must be entirely arbitrary, since the several points (the stars) may be united in a hundred different ways, just as imagination directs; for instance, the best known of all the constellations, the Great Bear, or the Wain, might just as well be made to represent a great variety of other things. It is enough that astronomers know what is meant by a certain constellation, so as to understand each other. The division of the heavens into constellations is like the division of a classic into pages and paragraphs. The ancient divisions of the constellations have been retained by the moderns, with the addition of such as have been newly discovered. When and where the first constellations were formed, is not known.

It is very probable that some of the most remarkable collections of stars, such as Charles's Wain, the Pleiades, Orion, &c., were formed into constellations, and had names given them, in very early ages.—Some of them, by their different appearances, serve to mark out the different seasons of the year, and, on that account, were not only considered as a kind of directory for the commencement of ploughing, sowing, and other operations of husbandry, but were also regarded as having a great influence on the temperature of the air, and the fertility of the earth.—Hence, from their being signs, pointing out the times of the year when heat or cold, dryness or moisture, predominated, they were regarded as the causes of these states of the atmosphere. They were also imagined to have dominion over minerals, vegetables, and animals; over the complexions, constitutions, and even the dispositions of mankind. This opinion obtained credit the more easily, as the sun, moon, planets, and stars were believed to be of a divine nature, insomuch, that some persons conceived that they were inhabited by an inferior kind of deities, who governed their motions, and directed their influences; while others thought that they were animals, each of which had a living soul; and others again supposed that they were animated by a part of the substance of the Supreme Being. Each of these notions led mankind to pay them a sort of religious worship.

The Egyptians divided the heavens into several regions, which they called the stations, or mansions, of their gods. They worshipped the heavenly bodies, and more especially the sun and moon, which they called their *great gods*, denominating the sun *Osiris*, and the moon *Isis*. They also imagined that they found in various animals, some qualities corresponding to the motions, appearances, or influences of the sun, moon, and some of the stars; hence they were induced not only to use those animals in their hieroglyphic representations of their deities, but also to pay them divine honours, and denominate the constellations from them. The Greeks, who learned astronomy of the Egyptians, retained several of their figures, as the ram, the bull, the dog, &c., but accommodated almost all of them to the fabulous history of their gods and heroes, whom they placed among the stars. The Romans imitated them, and the poets of both nations have given us wild and romantic fables about the origin of the constellations, probably derived from the hieroglyphics of the Egyptians, and transmitted, with some alterations, from them to the Greeks. Many of the figures that occur among our present constellations were originally Egyptian.

The names which the Chinese and Japanese give to the groups of stars forming our constellations, are very different from those which we have given them. Some Arabians, too, though they received their astronomy from the Greeks, changed the names of the constellations, from a superstitious notion, that it was unlawful to draw any human figure. The zeal of some Christian philosophers has induced them to endeavour to drive the heathen deities and heroes from the skies. The venerable Bede gave the names of the twelve apostles to the twelve signs of the zodiac. Judas Schillerius, in 1627, completed the reformation, and gave Scripture names to all the constellations in the heavens. Weigelius, professor of mathematics in the university of Jena, made a new order of constellations, converting the firmament into a *cœlum heraldicum*, and introducing the arms of all

the princes of Europe among the constellations. The more intelligent astronomers, however, never approved of innovation, because it tended to introduce confusion into the science. The old constellations, therefore, are for the most part still retained.

Ptolemy enumerates in his *Almagest*, forty-eight constellations, which are still called the *Ptolemæan*. They are the following:—1. The twelve signs of the zodiac. 2. Twenty-one constellations found in the northern hemisphere—the Great Bear (*Ursa Major*, the Wain), the Little Bear (*Ursa Minor*), Perseus, the Dragon, Cepheus, Cassiopeia, Andromeda, Pegasus, Equus (Horse's Head), the Triangle, the Waggoner (*Auriga*), Boötes, the Northern Crown (*Corona Borealis*), Ophiuchus, the Serpent (*Serpentarius*), Hercules, the Arrow (*Sagitta*), the Lyre, the Swan, (*Cygnus*), the Dolphin, the Eagle (*Aquilla*). 3. Fifteen constellations in the southern hemisphere—Orion, the Whale (*Cetus*), Eridanus, the Hare (*Lepus*), the Great Dog (*Canis Major*), the Little Dog (*Canis Minor*), Hydra, the Cup (*Crater*), the Crow (*Corvus*), the Centaur, the Wolf (*Lupus*), the Altar (*Ara*), the Southern Fish (*Piscis Australis*), the Argo, the Southern Crown (*Corona Australis*). The poets of antiquity very ingeniously connected the most popular fables of mythology with the different constellations. Some of the constellations, however, have been changed: and even the ancients sometimes added new ones, such as the Hair of Berenice and the Antinous. Much still remained for modern astronomers to do. Hevelius introduced the twelve following new constellations:—the Shield of Sobiesky, the Squirrel, Camelopardalus, the Sextant, the Greyhounds, the Little Lion, the Lynx, the Fox and the Goose, the Lizard, the Little Triangle, Cerberus, and Mons Mænalus. When the Europeans began to navigate the southern hemisphere, many new stars of course appeared to them, which they never had seen in Europe. Thus twelve new constellations were added in the 16th century—the Indians, Crane, Phœnix, Fly, Southern Triangle, Bird of Paradise, Peacock, American Goose, Hydrus or Water-Snake, Sword-Fish, Flying-Fish, Chamæleon. Halley, in 1675, during his stay at St. Helena, added the Royal Oak (*Robur Carolinum*); and Lacaille, in 1750, during his stay at the Cape of Good Hope, added the fourteen following:—Officina Sculptoria, Fornax Chemica, Horologium, Reticulus, Rhomboidalis, Equuleus Pictorius, Cæla Praxitelis, Pyxis Nautica, Octans Hadleianus, Machina Pneumatica, Circinus (the Compass), Quadra Euclidis, Telescope, Microscope, and Table Mountain. To these have been added the Lapland Reindeer, the Hermit, the Brandenburg Sceptre, the Telescope of Herschel, the Shield of Poniatowsky, or Taurus Poniatowsky, the Honour of Frederick, and others, which cannot well be enumerated here, as their names have not been sanctioned by all nations. Thus the professors of Leipsic made of a part of Orion the constellation of Napoleon, but it did not come into use. The different stars of a constellation are marked by Greek letters. Several have also articular names. They are also divided according to their apparent magnitude; thus we speak of stars of the first, second, and third, up to the sixth magnitude. The last are the smallest visible to the naked eye. Orreries are frequently constructed which exhibit the pictorial appearance of these astronomical signs in the most beautiful manner. One of the best was made for Mr. Bartley, and those who were fortunate enough to hear the highly poetical illustrations introduced by that clever dramatic performer, must regret that it was combined with so little of practical science.

In the above sketch, we give a representation of the constellation. It is one of a series which very beautifully illustrates the clusters of stars; their situation being indicated by holes, pierced by angular punches regulated to the size of the star. Behind the drawing is placed a piece of tissue paper, which gives an even tint to the whole.

Constitution, in *medicine*; the general condition of the body, as evinced by the peculiarities in the performance of its functions: such are the peculiar predisposition to certain diseases, or liability of particular organs to disease, the varieties in digestion, in muscular power and motion, in sleep, in the appetite, &c. Some marked peculiarities of constitution are observed to be accompained with certain external characters, such as a particular colour and texture of the skin, and of the hair, and also with a peculiarity of form and disposition of mind; all of which have been observed from the earliest time, and divided into classes, and which received names, during the prevalence of the humoral pathology, that they still retain.

Consumption, in *medicine*. See Atrophy.

Contagion. This word properly imports the application of any poisonous matter to the body through the medium of touch. It is applied to the action of those very subtile particles arising from putrid substances, or from persons labouring under certain diseases, which communicate the diseases to others; as the contagion of putrid fever, the effluvia of dead animal or vegetable substances, the *miasmata* of bogs and fens, the *virus* of small-pox, *lues venerea*, &c., &c.

The principal diseases excited by poisonous *miasmata* are, intermittent, remittent and yellow fevers, dysentery and typhus. The last is generated in the human body itself, and is sometimes called the *typhoid fomes*. Some *miasmata* are produced from moist vegetable matter, in some unknown state of decomposition. The contagious *virus* of the plague, small-pox,

measles, chin-cough, *cynanche maligna*, and scarlet fever, as well as of typhus and the gaol fever, operates to a much more limited distance through the medium of the atmosphere than the marsh *miasmata*. Contact of a diseased person is said to be necessary for the communication of plague; and approach within two or three yards of him for that of typhus.

The Walcheren *miasmata* extended their pestilential influence to vessels riding at anchor, fully a quarter of a mile from the shore. The chemical nature of all these poisonous effluvia is little understood. They undoubtedly consist, however, of hydrogen united with sulphur, phosphorus, carbon, and azote, in unknown proportions and unknown states of combination. The proper neutralizers or destroyers of these gasiform poisons are, nitric acid vapour, muriatic acid gas and chlorine. The two last are the most efficacious, but are best used in situations from which the patients can be removed at the time of the application. Nitric acid vapour may, however, be diffused in the apartments of the sick without much inconvenience. Bed-clothes, particularly blankets, can retain the contagious matter, in an active state, for almost any length of time. Hence they ought to be fumigated with peculiar care. The vapour of burning sulphur or sulphurous acid is used in the East against the plague. It is much inferior in power to those already named. There does not appear to be any distinction commonly made between contagious and infectious diseases.

The infection communicated by diseased persons is usually so communicated by the product of the disease itself; for instance, by the matter of the small-pox; and therefore many of these diseases are infectious only when they have already produced such matter, but not in their earlier periods. In many of them, contact with the diseased person is necessary for infection, as is the case with the itch, syphilis, canine madness; in other contagious diseases, even the air may convey the infection, as in the scarlet fever, the measles, the contagious typhus, &c. In this consists the whole difference between the fixed and volatile contagions.

A real infection requires always a certain susceptibility of the healthy individual; and many infectious maladies destroy, forever, this susceptibility of the same contagion in the individual, and, accordingly, attack a person only once, as the small-pox, measles, &c. Other contagious diseases do not produce this effect, and may, therefore, repeatedly attack the same person, as typhus, itch, syphilis, and others. Sometimes one contagious disease destroys the susceptibility for another, as the cow-pock for the small-pox. In general, those parts of the body which are covered with the most delicate skin, are most susceptible of contagion; and still more so are wounded parts, deprived of the epidermis. Against those contagious diseases which are infectious through the medium of the air, precautions may be taken by keeping at the greatest possible distance from the sick, by cleanliness and fearlessness; but most completely by the vigilance of the health-officers, by fumigations according to the prescriptions of Guyton-Morveau, and more especially by the wonderful disinfectant powers of the chlorides of lime and soda. We can more easily secure ourselves against such contagious diseases as are infectious only in case of contact, by means of cleanliness, caution in the use of vessels for eating and drinking, of tobacco-pipes, of wind-instruments, beds, and clothes. No general preservative against contagious diseases is known, though many are offered for sale by quacks. The examination of the persons intended for nurses of infants is very necessary, as thousands of children may be infected by contact with them, and the cause of the disorder remain unknown.

Contraction, in *physics*; the diminishing the extent or dimensions of a body, or the causing its parts to approach nearer to each other, in which sense it stands opposed to dilatation or expansion. Water, and all aqueous fluids are gradually contracted by a diminution of temperature, until they arrive at a certain point, which is about 8° above the freezing point; but below that point they begin to expand, and continue to do so according as the temperature is lowered. Similar effects have been observed with regard to some metals. Speaking of contraction, a remarkable phenomenon, of considerable importance in manufactures, presents itself to our notice. It is the hardness which certain bodies acquire in consequence of a sudden contraction, and this is particularly the case with glass and some of the metals. Thus glass vessels, suddenly cooled after having been formed, are so very brittle, that they hardly bear to be touched with any hard body. The cause of this effect is thus explained by Dr. Young:—"When glass in fusion is very suddenly cooled, its external parts become solid first, and determine the magnitude of the whole piece, while it still remains fluid within. The internal part, as it cools, is disposed to contract still farther, but its contraction is prevented by the resistance of the external parts, which form an arch or vault round it, so that the whole is left in a state of constraint; and as soon as the equilibrium is disturbed in any one part, the whole aggregate is destroyed." Hence it becomes necessary to anneal all glass, by placing it in an oven, where it is left to cool slowly; for, without this precaution, a very slight cause would destroy it. The Bologna jars, sometimes called proofs, are small thick vessels made for the purpose of exhibiting this effect; they are usually destroyed by the impulse of a small and sharp body; for instance, a single grain of sand, dropped into them, and a small body appears to be more effectual than a large one; perhaps because the larger one is more liable to strike the glass with an obtuse part of its surface.

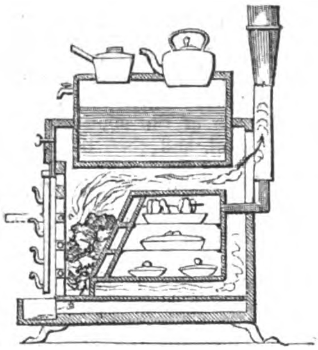
Contravallation; a line formed in the same manner as the line of circumvallation, to defend the besiegers against the enterprises of the garrison, so that the troops carrying on the siege lie between the lines of circumvallation and contravallation. As the line of circumvallation must be out of the reach of cannon shot from the place besieged, its circumference is necessarily so great as to render both its erection and its defence difficult. It is, therefore, seldom resorted to, and a corps of observation is generally preferred.

Converging Rays, in *optics*, those rays that, issuing from diverse points of an object, incline towards one another, till, at last, they meet and cross, and then become diverging rays.

Converging Series, in *mathematics*; series whose terms decrease the farther they proceed.

Converse, in *mathematics*. One proposition is called the converse of another, when, after a con-

under the name of portable kitchens, one of which is represented in the engraving beneath.



Our engraving shows the section of a stove invented by Mr. Williams, furnished with a grate, at the back of which there is an air passage, forming one side of the oven. Flues pass under and over the oven, and lead to the chimney. The boiler is at top, and there are falling bars in front of the grate, and there is a sliding plate to be occasionally lowered to act as a blower.

The first feature of novelty proposed is, the air-channel, which is supplied by an aperture with a slider opening from the outside near the bottom. The atmospheric air thus admitted, passes along the lower compartment, and becomes heated, then upwards into the second; returning again along that channel, it then rises into the third, and proceeds from thence through the upper part of the oven, and escapes by a small pipe into the chimney. The advantage of this air-channel is, that the fire of the grate will not be allowed to come in immediate contact with the oven, and also, that in passing through the top of the oven, it will cause the meat in that compartment to be roasted, instead of baked.

The second feature is the introduction of two sliders or dampers into the flues; and when it is required to throw the greatest heat into the boiler then the damper of the lower flue is closed, and the flame and smoke passed through the upper flue; but when, on the contrary, the heat of the oven is to be increased, the upper damper is closed, and the flame, smoke, and other vapour passed through the flue under and behind the oven. Apertures are made in the upper part of the boiler for introducing the bottom of a tea-kettle or saucepan, which are to be made to boil by the heat of the steam.

The third feature is two falling bars in front of the grate, which being let down, as shown by dots, form a ledge to set any vessel upon for stewing, &c. When it is required to increase the strength of the fire, the plate is slidden down over the upper part of the grate, which then acts as a blower.

Copaiba, or balsam of copaiba; a liquid resinous juice, issuing from incisions made in the trunk of a tree growing in the West Indies, of which there is only one species.

The juice is clear and transparent, of a whitish or pale yellowish colour, an agreeable smell, and a bitterish pungent taste. It is usually about the consistence of oil; when long kept, though retaining its transparency, it becomes nearly as thick as honey; and, unlike other resinous juices, does not acquire a solid state.

Genuine balsam of copaiba dissolves entirely in rectified spirits, especially if a little alkali be previously added to the liquor: the solution has a very fragrant smell. When distilled with water, it yields a large quantity of a limpid essential oil; and in a strong heat, without addition, an oil of a blue colour.

With respect to the medicinal properties of this balsam, it is said to be both corroborant and detergent. It strengthens the nervous system, tends to open the bowels, in large doses proves purgative, and promotes the secretion of urine. It has also been recommended, most injudiciously however, in dysentery, and in diseases of the chest or lungs. The dose of this medicine should not exceed from twenty to thirty drops. It may be conveniently taken when mixed with a thin syrup, or in the form of an emulsion, into which it may be reduced, by triturating it with a thick mucilage of gum arabic, till both ingredients are well incorporated, and then gradually adding a proper quantity of water.

Copal. This substance which deserves particular attention from its importance as a varnish, and which at first sight seems to belong to a distinct class from the resins, is obtained from the narrow-leaved or beach sumach, a tree which is a native of North America; but the best sort of copal is said to come from Spanish America, and to be the produce of different trees.

Copal is a beautiful white resinous substance, with a slight tint of brown. It is sometimes opaque, and sometimes almost perfectly transparent. When heated, it melts like other resins; but it differs from them in not being soluble in alcohol, or in oil of turpentine, without peculiar management. Neither does it dissolve in the fixed oils with the same ease as the other resins. It resembles gum animé a little in appearance, but is easily distinguished by the solubility of the latter in alcohol, and by its being brittle between the teeth, whereas animé softens in the mouth.

When copal is dissolved in any volatile liquid, and spread thin upon wood, metal, paper, &c., so that the volatile menstruum may evaporate, the copal remains quite transparent, and forms one of the most beautiful and perfect varnishes that can well be conceived. The varnish thus formed is called copal varnish, from the chief ingredient in it. Copal varnish used by the English japanners is made as follows. Four parts by weight of copal in powder are put into a glass matrass and melted. The liquid is kept boiling till the fumes, condensed upon the point of a tube thrust into the matrass, drop to the bottom of the liquid without occasioning any hissing noise as water does. This is a proof that all the water is dissipated, and the copal has been long enough melted. One part of boiling hot linseed oil (previously boiled in a retort without any litharge) is now poured into it, and well mixed. The matrass is then taken off the fire, and the liquid, while still hot, is mixed with about its own weight of oil of turpentine. The varnish thus made is transparent, but it has a tint of yellow, which the japanners endeavour to conceal by giving the white ground on which they apply it a shade of blue. It is with this varnish that the dial-plates of clocks are covered after having been painted white.

Copeck; a Russian copper coin, so called from the impression of St. George bearing a lance. A

hundred of them make one ruble. The value of the copper coin, compared with the assignation-ruble, varies in the different governments.

COPPER is of a red colour, with a tinge of yellow, having considerable lustre, but liable to tarnish and rust from exposure to the air. It is moderately hard, and has considerable ductility and malleability. Its specific gravity is 8.66. It has a sensible odour, especially when heated or rubbed, a styptic, unpleasant taste, and is peculiarly poisonous to animals. Copper melts at a full white heat, and, by slow cooling, may be crystallized. It suffers oxidation at a lower temperature from the action of the air, thin scales of oxide forming on its surface when it is heated to redness. At a higher heat, it burns with a green flame. Exposure to air and humidity, at the natural temperatures, converts it into a green rust, which is the oxide combined with a portion of carbonic acid.

There are two oxides of copper. The protoxide is of a red colour, and occurs native, in the form of octoedral crystals, in the mines of Cornwall. It is also prepared artificially, by mixing 64 parts of metallic copper, in a state of fine division, with 80 parts of the peroxide, and heating the mixture to redness in a close vessel; or by boiling a solution of the acetate of copper with sugar, when the peroxide is gradually deoxidized, and subsides as a red powder.

It consists of one atom, or proportional, of copper 64, and one of oxygen, 8, = 72. The sulphuric, muriatic, and probably several other acids, form with it salts, which, for the most part, are colourless. On exposure to the air, they attract oxygen, and are rapidly converted into per-salts. The peroxide of copper is also found native, and may be prepared artificially by calcining metallic copper, by precipitation from the per-salts of copper, by means of pure potash, or by heating the nitrate of copper to redness. It is composed of one atom of copper 64, and two of oxygen 16, = 80. It varies in colour from a dark-brown to a bluish-black, is insoluble in water, and does not affect the vegetable blue colours. It undergoes no change by heat alone, but is readily reduced to the metallic state by heat and combustible matter. It combines with nearly all the acids, and most of its salts have a green or blue tint. It is soluble, likewise, in ammonia, forming with it a deep blue solution—a property by which the peroxide of copper is distinguishable from all other substances.

Metallic copper is oxidated and dissolved by the greater number of the acids, and forms with them, in general, soluble and crystallizable salts. Sulphuric acid, either concentrated or diluted, oxidates it, and combines with the peroxide, especially when assisted by heat.

The solution is of a blue colour, and, when evaporated, affords crystals in the form of rhomboidal prisms. This salt is the *blue vitriol* of commerce, and is usually obtained, either by evaporation of the solution of it, formed by the infiltration of water through copper mines, or by exposure of sulphuret of copper to the action of air and humidity, until the sulphur is converted into sulphuric acid, and the metal is oxidated and combined with it. Nitric acid acts on copper with great energy, the metal attracting a portion of its oxygen, nitric oxide gas being disengaged, and the oxide combining with the remaining acid. The solution, when evaporated, affords prismatic crystals, of a deep green colour, deliquescent, and easily soluble in water. From the facility with which it parts with oxygen, it acts with energy on several substances. Thus it detonates when struck with phosphorus, and it burns several of the metals. If wrapped in tinfoil, the tin is oxidated with such rapidity as to be attended with inflammation.

Muriatic acid dissolves copper slowly when the air is admitted: if it is excluded, the action is very inconsiderable, unless heat is applied. The solution is of a fine green colour, and, by evaporation, slender prismatic crystals are obtained, which are deliquescent, and very soluble in water. The combinations of peroxide of copper with phosphoric, carbonic, and other acids, are effected by adding to a solution of nitrate, or sulphate of copper, a solution of a neutral salt, containing the acid with which the copper is designed to be combined. Copper is slowly oxidated by a number of weaker acids, as by some vegetable juices, when acted on by them with the admission of air. Acetic acid, or vinegar in particular, forms an important compound with the oxide of copper. To obtain it, copper plates are exposed to the fumes of vinegar. A crust is soon formed of a green colour, which is the *verdigris* of commerce.

All the salts of copper are decomposed by the alkalies and earths. Potash, soda, and the alkaline earths, throw down precipitates, which are of various shades of green or blue, according to the quantity of alkali added, the colour being green, if a small quantity is added, and becoming blue from a larger quantity. These precipitates are sub-salts, the alkali attracting the greater portion of the acid, but the oxide precipitated still retaining a portion of the acid combined with it.

The action of ammonia upon the salts of copper is more remarkable. It first abstracts a portion of the acid, and throws down a green or blue precipitate, which is a sub-salt; but, when added in larger quantity, it redissolves this precipitate, and forms a transparent solution, of a very deep-blue colour, which, when evaporated, affords fine blue crystals. A triple compound, used in medicine under the name of *ammoniuret of copper*, is prepared by triturating together two parts of sulphate of copper with one part of carbonate of ammonia, the mass becoming soft from the mutual action of the two salts, the carbonic acid being disengaged with effervescence, and the triple compound of sulphuric acid, oxide of copper, and ammonia, being obtained of a deep violet-blue colour.

Copper is precipitated in its metallic state, from its saline solutions, by zinc and iron; either of these metals attracting the oxygen which serves as the medium of its union with the acid of the solution. Its oxide is precipitated by albumen, and the precipitate is almost inert; hence the whites of eggs have been recommended as an antidote to the poisonous salts of copper. The best mode of detecting copper, when suspected to be present in mixed fluids, is by sulphuretted hydrogen. The sulphuret, after being collected, should be placed on a piece of porcelain, and digested in a few drops of nitric acid.

A sulphate of copper is formed, which, when evaporated to dryness, strikes the characteristic deep blue on the addition of a drop of ammonia. Copper and sulphur unite by fusion, the combination being attended with the evolution of heat and light. A bisulphuret of copper also exists in copper pyrites.

Copper combines with a great number of the metals by fusion. It communicates hardness to gold and silver, without much impairing their ductility, or debasing their colour, when in small proportion; hence it is employed in the standard alloys of these metals, that of gold containing one-twelfth, that of silver one-sixteenth, of the mass. With platina, it forms an alloy, ductile, and susceptible of a fine polish. With tin, it forms several valuable alloys, which are characterized by their sonorousness.

Bronze is an alloy of copper, with about 8 or 10 per cent. of tin, together with small quantities of other metals, which are not essential to the compound. Cannons are cast with an alloy of a similar kind, and the ancient bronze statues were of nearly the same composition.

Bell-metal is composed of 80 parts of copper and 20 of tin. The Indian gong, so much celebrated for the richness of its tones, contains copper and tin in this proportion. The proportion of tin in bell-metal varies, however, from one-third to one-fifth of the weight of the copper, according to the sound required, the size of the bell, and the impulse to be given. M. d'Arcet has discovered that bell-metal formed in the proportion of 78 parts of copper, united with 22 of tin, is, indeed, nearly as brittle as glass, when cast in a thin plate or gong; yet, if it be heated to a cherry red, and plunged into cold water, being held between two plates of iron, that the plate may not bend, it becomes malleable. Gongs, cymbals, and tamtams have been manufactured with this compound.

Brass. Copper and zinc unite in several proportions, forming alloys of great importance in the arts. The best brass consists of four parts of copper to one of zinc; and, when the latter is in greater proportion, compounds are formed called *tombac, Dutch gold*, and *pinchbeck*. An alloy called *Bath metal* is made by adding 9 pounds of zinc to 32 of brass; and an extremely pale, nearly white metal, used by the button-makers of Birmingham, under the name of *platina*, by adding 5 pounds of zinc to 8 of brass. The brothers Keller, who were very celebrated statue-founders, used an alloy, 10,000 parts of which contained 9140 of copper, 553 of zinc, 170 of tin, and 137 of lead. Their castings are very celebrated, and some are of very large size, as the equestrian statue of Louis XIV., cast at a single jet, by Balthazar Keller, in 1699, which is 21 feet high, and weighs 53,263 French pounds. These statues are usually called *bronze* statues, although made of brass. Brass was well known to the Romans, under the name of *orichalcum*, who took advantage of its resemblance to gold, in robbing the temples and other public places of that precious metal. Thus Julius Cæsar robbed the capitol of 3000 pounds weight of gold, and Vitellius despoiled the temples of their gifts and ornaments, and replaced them with this inferior compound.

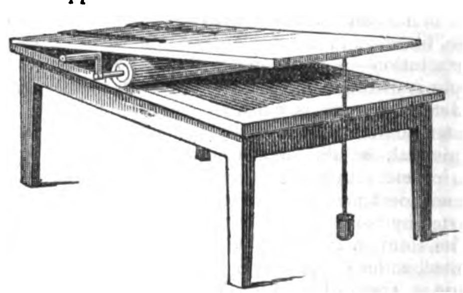
The art of *tinning* copper consists in covering that metal with a thin layer of tin, in order to protect its surface from oxydating. For this purpose, pieces of tin are placed upon a well-polished sheet of copper, which, if the process is skilfully conducted, adhere uniformly to its surface. The oxidation of the tin—a circumstance which would entirely prevent the success of the operation—is avoided by employing fragments of resin, or muriate of ammonia, and regulating the temperature with great care.

For an account of the ores of this metal, the reader is referred to the *Natural History* division of our work.

COPPERAS, or GREEN VITRIOL, is a mineral substance, formed by the decomposition of pyrites by the moisure of the atmosphere. Its colour is bright-green, and its taste very astringent. A solution of it in water, dropped on oak-bark, instantly produces a black spot. Copperas is occasionally found in grottoes, caverns, the galleries of mines, and other places. It is in much request with dyers, tanners, and the manufacturers of ink, and, for their use, is artificially prepared from pyrites. This mineral being moistened and exposed to the air, a crust is formed upon it, which is afterwards dissolved in water: from this the crystals of vitriol are obtained by evaporation. The principal use of vitriol is in dyeing woollen articles, hats, &c. black. It is the basis of ink, and is used in the manufacture of Prussian blue. If it be reduced to powder by the action of fire in a crucible, and mixed with powder of galls, it forms a dry portable ink.

We have, in the above short article, given the ordinary definition of the word *copperas*, though one more erroneous, both with regard to fact and theory, can hardly be conceived. In copperas there is *not one particle of copper*. It is, in truth, a *sulphate of iron*, and it may readily be formed by exposing iron to the action of sulphuric acid, which is but another name for the oil of vitriol of the shops. This is one out of many instances which might be adduced, of a false nomenclature which has been introduced by commercial men.

COPYING MACHINES. The most convenient mode of multiplying copies of a writing is by lithography, and this mode is much used by merchants and others in preparing circulars; also in the different departments of government. In Mr. Hawkins's polygraph, two or more pens are so connected as to execute, at once, two or more copies. Mr. Watts's copying machine is a press, in which moistened bibulous paper is forced into close contact with freshly written manuscript. The writing is, of course, reversed, but, the paper being thin, the characters can be read on the opposite side.



A simple copying machine, acting on the same principle as that of Mr. Watt, but much cheaper, is shown above. Its use must be obvious on the slightest inspection. Dr. Franklin used to cover writing, while moist, with fine powdered emery, and pass the sheet through a press in contact with a plate of pewter or copper, which thus became sufficiently marked to yield impressions, as in the common mode of copperplate printing.

CORDAGE; a general term for ropes, or rather small cords. They consist of twisted fibres, and at

an early period was, in all probability, only thongs of leather. These primitive ropes were retained by the Caledonians in the third century. The nations to the north of the Baltic had them in the ninth or tenth centuries; and the inhabitants of the western isles of Scotland make use of them at present; cutting the skin of a seal, or the raw and salted hide of a cow into long pieces, and fastening the plough to their horses with them, or even twisting them into strong ropes of twenty or thirty fathoms length.—But these, in the south of our island, and on the continent, were early superseded by the use of iron chains. The very maritime and commercial nation the Veneti, that were so intimately connected with the Belgæ of Britain, used iron chains for their cables in the days of Cæsar. But in the more distant and refined countries of the south, both thongs and these had given place to the use of vegetable threads, and the arts of combining them into strength. In this manner the Greeks appear to have used the common rushes of their country, and the Carthagenians the spartium or broom of Spain. And as all the cordage of the Romans was made of these materials at their last descent on our island, so the art of manufacturing them would be necessarily introduced with the Roman settlements among the Britons.—Under the direction of the Roman artists their thongs of leather would naturally be laid aside, and the *junci*, or rushes of the plains, worked up into cordage.

It is a curious circumstance, that a patent has lately been taken out for an invention which at once reminds us of the cordage of many of the uncultivated southern tribes. The object of this invention is to produce a rope, or sail cloth, which shall be impervious to water

The patentee proposes to employ, as the substance of his improved ropes or cordage, a vegetable production, called *silk grass*, which, when dried is to be beaten and heckled in the same manner that flax or hemp is usually prepared. In the process of preparing the grass, it is proposed to introduce a bituminous and gummy material, which is intended to saturate the fibres of the grass, for the purpose of preserving the ropes, cordage, or sail cloth, or any other fabric made from it, when exposed to the effects of damp.

This gummy material is to be compounded of the milk of a tree called the *ficus indica*, with *asphultum*, or *bitumen judaicum*, and *cocoa nut oil*. The proportions are to about twenty-five gallons of the milk, one gallon of the oil, and from one to twenty gallons of the bitumen, according to circumstances.

These substances when properly combined, which may be done over a slow fire, constitute a gummy material, into which the fibres of the grass may be dipped while heckling, and it also may be applied in twisting or spinning. It is likewise proposed that the workmen in twisting the strands of cord, shall dip their hands in the material, and work it well into the fibres and texture of the rope.

When this gummy material has become dry, it will resist water, and prevent the rotting effects of damp upon the fibres of the rope, cordage, sail cloth, or other articles manufactured from it.

Cordovan; a fine leather, which took its name from the city of Cordova, where it was manufactured in large quantities. Much is now made in the Barbary States.

Coriander. This seed has, when fresh, a very unpleasant smell. It is, on the contrary, very agreeable and aromatic when dry. It acts in the same manner as aniseed, &c., and enters into several medicinal compounds. Its infusion is occasionally employed as a sudorific. It is used, likewise, as a rective of certain purgatives.

Corinthian Order. See Architecture.

Cork is the external bark of a species of oak, which grows in Spain, Portugal, and other southern parts of Europe, and is distinguished by the fungous texture of its bark, and the leaves being evergreen, oblong, somewhat oval, downy underneath, and waved. The principal supply of cork is obtained from Catalonia in Spain. In the collecting of cork, it is customary to slit it with a knife at certain distances, in a perpendicular direction from the top of the trees to the bottom; and to make two incisions across, one near the top, and the other near the bottom of the trunk. For the purpose of stripping off the bark, a curved knife, with a handle at each end, is used. Sometimes it is stripped in pieces the whole length, and sometimes in shorter pieces, cross cuts being made at certain intervals.

In some instances, the perpendicular and transverse incisions are made, and the cork is left upon the trees, until, by the growth of the new bark beneath, it becomes sufficiently loose to be removed by the hand. After the pieces are detached, they are soaked in water, and, when nearly dry, are placed over a fire of coals, which blackens their external surface. By the latter operation, they are rendered smooth, and all the smaller blemishes are thereby concealed; the larger holes and cracks are filled up by the introduction of soot and dirt. They are next loaded with weights to make them even, and subsequently are dried and stacked or packed in bales for exportation.

The uses of cork were well known to the ancients, and were nearly the same to which it is applied by us. Its elasticity renders it peculiarly serviceable for the stopping of vessels of different kinds, and thus preventing either the liquids therein contained from running out, or the external air from passing in. The use of cork for stopping glass bottles is generally considered to have been introduced about the 15th century.

The practice of employing this substance for jackets to assist in swimming is very ancient; and it has been applied in various ways towards the preservation of life when endangered by shipwreck. The cork jacket, revived from an old German discovery by Mr. Dubourg, to preserve the lives of persons in danger of drowning, is constructed as follows:—Pieces of cork, about three inches long by two wide, and the usual thickness of the bark, are enclosed between two pieces of strong cloth or canvass, and formed like a jacket without sleeves; the pieces of cloth are sewed together round each piece of cork, to keep them in their proper situations; the lower part of the jacket, about the hips, is made like the same part of women's stays, to give freedom to the thighs in swimming; it is made sufficiently large to fit a stout man, and is secured to the body by two or three strong straps sewed far back on each side, and tied before; the strings are thus placed to enable any wearer to tighten it to his own convenience.

The floats of nets used for fishing are frequently made of cork. Pieces fastened together make buoys, which, by floating on the surface of the water, af-

ford directions for vessels in harbours, rivers, and other places. In some parts of Spain, it is customary to line the walls of houses with cork, which renders them warm, and prevents the admission of moisture. In the cutting of corks for use, the only tool employed is a very broad, thin, and sharp knife; and, as the cork tends very much to blunt this, it is sharpened on a board by one whet or stroke on each side, after every cut, and now and then upon a common whetstone. The corks for bottles are cut lengthwise of the bark, and consequently the pores lie across. Bungs, and corks of large size, are cut in a contrary direction: the pores in these are therefore downward—a circumstance which renders them much more defective in stopping out the air than the others. Cork-bark is almost entirely imported from Italy, Spain, and Portugal. In 1828, the imports were, from Italy, 81,035 cwt., Spain, 12,935 cwt., and Portugal, 5,029 cwt.

Cork is formed into soles for shoes; it is also ingeniously used, on account of its lightness, when an amputation of the human leg has been necessary, to supply the deficiency; the Spaniards line stone walls with it, which not only renders their houses very warm, but corrects the moisture of the air. The Egyptians made coffins of it, which being covered in the inside with a resinous composition, preserved their dead bodies. It is burnt to make that light black substance called Spanish black, from its first having been made in Spain.

Cork received into the stomach, in its crude state, is very deleterious: but after it has undergone certain processes, it is used in medicine. It contains a small quantity of very powerful acid, called suberic acid, which is different from all the other acids; but which easily unites with the alkalies and earths.

The business of cork-cutting, or the manufacturing of corks, though it is thought one of the most dirty, is not one of the least profitable; it is likewise easy in the acquirement. The cork, after being pressed into square pieces, is received by the cork-cutters, and if not sufficiently flat for their purpose, they "lay" it again over a fire in their "burning yard," turning the convex part to the flame; the heat, by twisting the edges of the bark, counteracts the natural bend, and compels it to receive a flat form. During this operation, a considerable degree of attention is paid to smoothing it, and particularly again to cover its defects. It is next cut into slips, narrow or wide, according to the intended cork, bung, or tap, for such are the names of the general divisions in this business. The use of the two former is well known, the latter is used for stopping the tap-holes of barrels, as the name implies. These slips are again cut into squares, of a length proportioned to the use they are intended for. This operation is performed by one man, from whom they are handed forward to several others. A farther division of corks takes place, of these different sorts, according to their lengths, and are denominated short, short long, and full long. The cork maker places himself before the table or plank, on which is fastened a board about three inches thick, four broad, and twelve long; immediately on a line with his left hand is a piece of wood rising about four inches from the board, and fixed about the middle of it, on which the cork is laid after being cut as above. This wood not only supports the cork, and is as a guide to the workman, but by its elevation above the board, gives room for the knife to cut a part of the cork in a smooth and circular manner.

Corn, in *rural economy;* the grains or seeds of plants, which are separated from the ear, and used chiefly for making bread.

There are several species of corn, such as wheat, rye, barley, oats, millet and rice, maize, or Indian corn, &c., each of which will be mentioned in its alphabetical order: we shall, therefore, in this place, not enter into any particulars relative to its culture, confining ourselves solely to such points as relate equally to the different species. We cannot but animadvert upon the injudicious practice of cutting corn in cold autumns, before it is perfectly ripe; as experience has proved, that if left standing, the ears will continue to fill, and become heavier even during the autumnal frosts. Were this latter method adopted, a much greater proportion of flour might be produced, and the grain would neither shrink nor shrivel, in barns or granaries; it might, at the same time, be prevented from rotting, on account of its immaturity, and the softness or moisture which are the necessary consequence.

Notwithstanding the great care and attention which the husbandman may bestow on the cultivation of corn, his expectations of a plentiful harvest are often frustrated by a variety of disorders and accidents, to which corn is peculiarly liable.

The first and most formidable is the smut, which is caused by vermin breeding in the grain, and thus destroying its substance. Their propagation, besides other causes, is evidently facilitated by laying on the soil too large a quantity of crude dung; which, becoming mouldy, promotes the generation of the smut animals.

Various experiments have been accordingly tried to eradicate this noxious distemper, with different degrees of success, a few of which we shall enumerate. In the greater part of the counties of Devon and Cornwall, on the evening before the wheat is intended to be sown, it is laid on the floor in a heap, on which is poured a solution of lime, slaked with boiling water, and reduced to the consistence of cream: both are then mixed, and left together till morning, by which time the wheat is dry and fit to be sown.

In other parts of the same counties the wheat is steeped either in fresh or salt water, for twelve, eighteen, or twenty-four hours, when it is put to to drain for an hour or two; after which, powdered lime is sifted over it, the whole being well mixed with a shovel: it is then thrown together in a heap, to dry previously to its being sown. Few farmers, however, soak it in lime, and a still smaller number of them substitute animal urine, soap-boilers' lye, &c. In several other counties there prevails a general practice of employing brine, strong enough to float an egg, to which powdered lime is added, till it acquires an unctuous consistence. This composition is mixed with the wheat, the evening before it is committed to the ground. In Yorkshire some farmers render the solution thicker, by the addition of lime, while others either sprinkle the wheat with it, or steep and wash the former, then sift lime over it, and mix them as before. Another method is, to put seventy gallons of water into a tub, at the bottom of which is a hole provided with a staff and tap-hose, as in brewing; to this is to be added half a hundred weight of limestone, and the whole well stirred for half an hour, when it is suffered to stand about

thirty hours. It should then be drawn off into another tub, and three pecks (forty-two pounds) of salt added, which, when dissolved, will make a strong pickle, fit for immediate use. But, if sea-water can be procured, half the quantity of salt will be sufficient. A basket of about two feet in diameter at the bottom, and twenty inches deep, should then be placed in the pickle, and the corn gradually immersed in small quantities, from one to two bushels, care being taken to skim off the light grains, which ought not to be sown, because many of them are infected with the smut. As soon as this operation is completed, the basket should be drawn up and drained for a few minutes over the liquor, when it may be repeated as often as the quantity of grain to be sown may require. This seed will be fit for the ground in twenty-four hours; but, where it is to be drilled, it should stand for forty-eight; and, if the driller meets with any difficulty in performing his work, it will be necessary to make the pickle more astringent, by adding lime. Seed thus prepared may be kept for five, six, seven, eight, or even ten days above ground, without any injury or inconvenience.

Corn is also liable to be grown, or sprouted, when it has partly begun to vegetate; for, if the whole of the grain were to bud, it would become unfit for being converted into bread. Hence it is very difficult to preserve sprouted corn, as the opening of the bud occasions it to heat, and the moisture it retains disposes it still more to undergo the process of fermentation. It is also more subject to be attacked by insects, on account of its being sweeter, more tender, and susceptible of heat, consequently more liable to receive their eggs. If left to itself, sprouted corn heats, ferments, and contracts an unpleasant smell and a bad colour; it also acquires a disagreeable sharp taste, which is communicated to the flour and bread; and, finally, grows mouldy and sour: in this state it is fit only for the manufacture of starch. Farther, it is ground with difficulty, clogs the millstones, chokes the bolting-cloths, and yields but little flour, which is soft and moist, and will not keep for any length of time, especially during warm weather.

We have entered thus largely into this subject, because, from the variableness of the climate of this country, considerable quantities of corn frequently become sprouted: we therefore extract, with satisfaction, the following interesting particulars, for remedying this serious evil, from an ingenious pamphlet published in France:—

Sprouted corn should by no means be stacked, but housed and threshed with the greatest expedition. Nor should it be put into a granary together with dry grain, as the latter will thus become moist. Care should also be taken to keep the place well aired; for, in the contrary case, even the latter cannot be preserved. As soon as sprouted corn is threshed, it should be spread upon the floor, and frequently turned, a door or window being left open to give vent to the steam. Sometimes it will be necessary to dry the corn in an oven, after the bread is removed, leaving the door half open, and turning the grain every ten minutes, to facilitate the evaporation of the moisture. When it is thus dried, it should be sifted, and not put into sacks or in heaps till it is properly cooled, as it will otherwise become mouldy.

Although some fastidious persons may object to the trouble occasioned by this mode of curing sprouted corn, yet, as eight or ten days' continual drying will preserve it for a whole year, and render both the bread and flour of a better quality, it surely merits the attention of every diligent husbandman, and will amply compensate his trouble and labour.

There is another disease that frequently attacks corn, which is usually termed burnt-grain. To these may be added what is called the spur, which affects both wheat and rye, but more especially the latter. The grains infested with it are thicker and longer than the sound ones; their outsides are either brown or black, and their surface rough. If spurred grain be opened, a white flour is perceivable in it, which is covered with another of a reddish or brown colour. The latter has some degree of consistence, but may be easily crumbled between the fingers. Naturalists are unable to ascertain, with precision, the cause of this distemper; but it is supposed to be occasioned by the bite or sting of an insect, that turns the corn into a kind of gall—a conjecture which is partly confirmed by the taste left on the tongue after eating such grain. The effects arising from the use of corn thus damaged, are said to be malignant fevers and gangrenes, in consequence of which the extremities of the body sometimes mortify, and spontaneously separate, without any pain or effusion of blood.

Among the various insects which prey upon corn, none is more destructive than the corn-butterfly, which is generated in a manner similar to that of the common butterflies. It settles on one grain, and after having totally consumed it, its existence is supposed to be prolonged by eating its own excrement. When it has attained its full growth, it is about one quarter of an inch in length, and half the thickness of the grain it has devoured. To exterminate this noxious insect, it has been recommended to prepare a very strong lye of wood-ashes, to which, when it becomes yellow, as much quick-lime should be added as will make it of a dusky white: while it is as hot as the hand can well bear it, the grosser part of the lime should be suffered to subside, and the lye poured off into a proper vessel; into which the corn is to be immersed by means of a basket, and quickly agitated, skimming off those grains which float on the surface. In the course of two or three minutes it may be taken out, and the basket, with its contents, suspended on two poles, to drain; after which it should be spread on the floor of a granary to dry, while a second basket undergoes a similar immersion. This simple process not only preserves the grain from rotting, but at the same time destroys all those insects that may have penetrated its substance.

With respect to the manner of preserving it, corn is very different from fruits; as, with proper care, it may be kept in granaries for several centuries. When it is designed to preserve the grain for a length of time, it should be well dried and cleaned before it is housed, care being taken to introduce air-holes on the top, and openings on the north and east of the granary. During the first six months, the corn should be carefully turned, once a fortnight at the least, to prevent it from heating; after which time it will be sufficient to turn it every month for about two years, when it will have exhaled all its igneous particles, and no apprehension need be entertained, unless from the air and adventitious moisture. Should it, nevertheless, heat from any unforeseen accident, so that there is apprehension of

its catching fire, such a misfortune may be easily prevented by making a hole in the middle, down to the floor, which will serve as a kind of chimney, or flue, for carrying off the heat. But, notwithstanding these precautions, it frequently happens that mites reduce the greater part of the grain to dust. This serious damage may be prevented by rubbing the adjacent places with fetid oils and herbs, such as garlic and dwarf-elder, the strong smell of which tends to expel them: besides, they may be exposed to the rays of the sun, which immediately destroys them. Among the numerous suggestions of foreign writers for preserving grain from the devastation of insects, we shall only mention those of smoking the store-houses with sulphur and tobacco (which, however, renders the corn unfit for vegetation); of covering the heaps of grain either with thin sail-cloth or old sheets, rolling them together when the vermin are settled on the surface, and exposing them to the voracious appetite of poultry in the farm-yard; of brushing them off the walls with hard brooms; of introducing ants, their greatest enemies, into the granary; of exposing dead lobsters; and, lastly, of ventilating the whole building, and frequently stirring the grain—remedies which, of all others, are perhaps the most efficacious methods of averting damage.

For the information of those dealers who avail themselves of arsenic, to destroy the rats and mice frequenting their corn-floors, we think it our duty to observe, that such a dangerous remedy ought never to be employed, as it has frequently produced the most fatal accidents, and as the excrements of the poisoned animals, where mixed with the grain, may likewise occasion disorders, the cause of which is not even suspected by physicians. Hence we advise those mercenary economists to substitute a remedy, which will be found equally effectual, and is perfectly safe: it merely consists in mixing two parts of pounded quick-lime, three parts of sugar, and placing at the side of it a separate shallow vessel, with water. The heating nature of this composition very speedily excites thirst, and induces those depredators to drink eagerly: in consequence of which the lime is slaked in their stomachs, and proves inevitably destructive.

When corn has been cleared of all impurities, in the manner above stated, it may be kept for a great number of years, nay, for ages, by depositing it in dry pits covered with strong planks: but the safer method is, to cover the heap with quick-lime, which should be gradually dissolved by sprinkling over it a small quantity of water. This causes the uppermost grains to sprout to the height of two or three inches, and incloses them with an incrustation, through which neither insects nor air can penetrate.

In order to ascertain the relative value of different species of grain, corn-dealers avail themselves chiefly of the combined criterion of weight and measure. In a commercial point of view, such a method is, doubtless, the most accurate; but, as it cannot be explained without entering into a very diffuse detail, accompanied with numerical tables, we shall communicate to our economical readers only a few practical directions, by an attention to which they may be sufficiently guided in the sale or purchase of corn in general.

1. Take a handful of grain from a heap, or sack, and compress it closely for a minute; then pass it from one hand to the other, and attentively examine its flavour, whether it possesses any peculiar smell different from that which is peculiar to the species; in which case you may conclude that it has been repeatedly exposed to moisture, and undergone a slight degree of fermentation. The flour obtained from such corn is deficient in measure, of an indifferent quality, and affords neither nourishing nor wholesome bread.

2. If, on pressure of the hand, the grains appear so solid and smooth that they in a manner glide through the fingers, without having any foreign smell or colour, in this case it may be pronounced perfectly dry, and in a good state of preservation.

3. Should, on the contrary, the corn feel rough, or if a number of grains, after compressing them by the dry hand, clog together and adhere to the fingers, it may be justly apprehended that such wheat, rye, &c. is damp, and possessed of all the bad properties before specified. (See AGRICULTURE and BREAD.)

CORN; a hardened portion of cuticle, produced by pressure; so called, because a piece can be picked out like a corn of barley. Corns are generally found on the outside of the toes, but sometimes between them, on the sides of the foot, or even on the ball. They gradually penetrate deeper into the parts, and sometimes occasion extreme pain, and, from the frequency of their occurrence, hold a prominent rank among the petty miseries of mankind, and frequently exert no small influence upon the temper of individuals.

No part of the human body, probably, has been injured so much by our injudicious mode of dress, as the feet, which have become, in general, deformed; so much so, that sculptors and painters can hardly ever copy this part from living subjects, but depend for a good foot almost solely on the remains of ancient art. To this general deformity of the foot belong the corns, produced by the absurd forms of our shoes and boots.

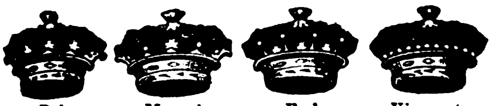
They appear, at first, as small dark points in the hardened skin, and, in this state, stimulants or escharotics, as nitrate of silver (lunar caustic), are recommended. The corn is to be wet, and rubbed with a pencil of the caustic every evening. It is well to have the skin previously softened. If the corn has attained a large size, removal by cutting or by ligature will be proper; if it hangs by a small neck, it is recommended to tie a silk thread round it, which is to be tightened every day, until the corn is completely removed. In all cases of cutting corns, very great precaution is to be observed. The feet ought always to be bathed previously. Mortification has, in many instances, resulted from the neglect of this precaution, and from cutting too deep. Another simple and generally very efficacious means, is the application of a thick adhesive plaster, in the centre of which a hole has been made for the reception of the projecting part. From time to time, a plaster must be added. Thus, the surrounding parts being pressed down, the corn is often expelled, and, at all events, is prevented from enlarging. Paring with files, rubbing with fish-skin, &c., have been likewise found effective. In large cities, as London, Paris, &c., people make a business of curing corns, and are called *Chiropodists*.

CORNET; a wind instrument, now but little known, having, for more than a century since, given place to the hautboy. There were three kinds of cornets,—the treble, the tenor, and the bass. The treble and tenor cornets were simple curvilineal tubes, about

three feet in length, gradually increasing in diameter from the mouth-piece towards the lower end. The bass cornet was a serpentine tube, four or five feet long, and increasing in diameter in the same manner.

CORNET, in military language, is the third officer in a company, in England and the United States.—He bears the colours of the troop. In the Prussian army, the name *cornet* is abolished.

CORONET; an inferior crown, belonging to the English nobility. The coronet of an English duke is adorned with strawberry leaves; that of a marquis has leaves, with pearls interposed; that of an earl raises the pearls above the leaves; that of a viscount is surrounded with pearls only; that of a baron has only four pearls. A series of coronets are represented beneath.



CORPORAL. This word is written in the same, or in a similar manner, in many languages, and, at first sight, would seem to be derived from *corps* (body); but it originates, in fact, from the French *caporal*, and the Italian *caporale*, which are derived from *capo*, the Italian form of the Latin *caput* (the head). The change of the first syllable, *ca*, into *cor*, is of much antiquity. Du Fresne uses the Low Latin term *corporalis*. From this author it appears, that *corporal* formerly signified a superior commander; but, like *captain*, and many other words, it has sunk in its dignity. A corporal is now a rank and file man, with superior pay to that of common soldiers, and with nominal rank under a sergeant. He has charge of one of the squads of the company, places and relieves sentinels, &c. Every company in the English service has three or four corporals. In armies in which privates may advance to the highest ranks, as in France, Prussia, &c., great care is taken in selecting corporals. In fact, they are officers of much importance, associating, as they do, with the privates, over whom, their superiority of rank gives them much influence. The feeling of military honour, good morals, and emulation in the discharge of duty, are, in a great degree, to be infused into the mass by means of the corporals.

A corporal of a man-of-war is an officer who has the charge of setting and relieving the watches and sentries, and who sees that the soldiers and sailors keep their arms neat and clean: he teaches them how to use their arms, and has a mate under him.

CORPUSCULAR PHILOSOPHY; that mode of philosophizing which endeavours to explain things, and to account for the phenomena of nature by the motion, figure, rest, position, &c. of the corpuscles, or the minute particles of matter.

Boyle reduces the principles of the corpuscular philosophy to the four following heads:

1. That there is but one universal kind of matter, which is an extended, impenetrable, and divisible substance, common to all bodies, and capable of all forms. On this head, Newton remarks thus: "All things considered, it appears probable to me, that God, in the beginning, created matter in solid, hard, impenetrable, moveable particles; of such sizes and figures, and with such other properties, as most conduced to the end for which he formed them; and that these primitive particles being solids, are incomparably harder than any of the sensible porous bodies compounded of them; even so hard as never to wear or break in pieces; no other power being able to divide what God made one in the first creation. While these corpuscles remain entire, they may compose bodies of one and the same nature and texture in all ages; but should they wear away, or break in pieces, the nature of things depending on them would be changed; water and earth composed of old worn particles, of fragments of particles, would not be of the same nature and texture now, with water, and earth composed of entire particles at the beginning. And therefore that nature may be lasting, the changes of corporeal things are to be placed only in the various separations, and new associations, of these permanent corpuscles."

2. That this matter, in order to form the vast variety of natural bodies, must have motion in some, or all its assignable parts; and that this motion was given to matter by God, the creator of all things; and has all manner of directions and tendencies. "These corpuscles, says Newton, have not only a vis inertiæ, accompanied with such passive laws of motion as naturally result from that force; but also are moved by certain active principles; such as that of gravity, and that which causes fermentation, and the cohesion of bodies."

3. That matter must also be actually divided into parts; and each of these primitive particles, fragments, or atoms of matter, must have its proper magnitude, figure, and shape.

4. That these differently sized and shaped particles have different orders, positions, situations, and postures, from whence all the variety of compound bodies arises. See ATOMICAL PHILOSOPHY.

CORPOSANT; a name given by the Italians to the electric flame which sometimes appears on the tops of the masts of vessels, and is also called *Castor and Pollux* and *St. Elmo's fire*.

CORPS; a word often used in military language, many of the terms of which are derived from the French, they having begun the organization of armies on the system which now prevails. The term is applied to various kinds of divisions of troops.—*Corps d'armée* is one of the largest divisions of an army—*Corps de garde;* a post occupied by a body of men on watch; also the body which occupies it.—*Corps de reserve;* a body of troops kept out of the action, with a view of being brought forward, if the troops previously engaged are beaten, or cannot follow up their victory, or are disorganized.—*Corps volant* (a flying body) is a body intended for rapid movements. It is always rather small.—*Corps de bataille* is the main body of an army, drawn up for battle between the wings.

CORPULENCE; the state of the human body, when loaded with an excessive quantity of flesh and fat. The flesh forms the muscular system; and, its extent being limited by the form of the particular muscular parts, its quantity can neither exceed nor fall below a certain bulk. The fat is much less limited, and the production and deposition of it is confined to no such definite form. The formation of the muscular fibres, or the change of blood into flesh, takes place in the capillary system, formed by the minutest portions of the arteries at their termination in the muscles. If blood is copiously furnished with nutritive matter, it is converted readily to muscular fibres

and fat. The secretion of fat depends, in a certain degree, on the state of the health.

Children and females have a larger proportion of it than adult men. It is promoted by rich diet, a good digestion, corporeal inactivity, tranquillity of mind, &c. There is, however, a certain diseased state of the system, which, independently of all these influences, will increase the production and deposition of fat. We see young people and men, even such as are intelligent, and continually engaged in active business, very corpulent.

The enormous corpulence of many men appears to bear no proportion to their food, and is evidently a disease, as many other secretions in the body; for example, the preparation and secretion of the bile, saliva, &c., are augmented by disease. Sandiford mentions an unborn child, in which he observed a monstrous mass of fat. Tulpius saw a boy five years old, who weighed 150 pounds. Bartholini makes mention of a girl, aged eleven years, who weighed above 200 pounds. In the *Philosophical Transactions*, mention is made of an Englishman, named Bright, who weighed 609 pounds. Daniel Lambert, of Leicester, was, probably, the heaviest man on record. He weighed 752 pounds. A Canadian, named Maillot, who exhibited himself at Boston, in 1829, weighed 619 pounds. Corpulency is often only the repletion of the cells of the cellular membrane with watery, gaseous, and vaporized matter, arising from a marked tendency to disease, and often the commencement of actual dropsy. Moderate corpulence (*embonpoint*, in French) is consistent with health, and is not opposed to beauty, as it prevents angularity and unevenness in the surface of the body, and gives the parts rotundity. For this reason, moderately corpulent women and men preserve a beautiful and youthful appearance longer than lean persons.

But if corpulence is excessive, it becomes troublesome, and, at length, dangerous. Water should then be drank instead of wine; milk, beer, and brandy should be avoided; active bodily exercise should be taken, and employment provided for the mind. Anxiety soon takes off superfluous fat, though grief sometimes produces it. In what cases medicine is to be resorted to, and what kinds should be used, must be left to the judgment of physicians. People sometimes resort to violent and injurious means to rid themselves of superfluous flesh. Madame Stich, the best actress in the theatre at Berlin, took poison to reduce her person to the right dimensions for performing Shakspeare's Juliet, and succeeded, though at the expense of her health. Instances of leanness as remarkable as those of corpulence are by no means rare. In 1825, a person was exhibited in England, who was not unaptly termed the living skeleton, and in 1830, a native of Vermont exhibited himself in the United States, under the same title. His legs and arms were almost entirely deprived of flesh. The man was about 45 years old, and weighed 60 pounds.

Corridor, in *architecture;* a gallery or long aisle leading to several chambers at a distance from each other, sometimes wholly enclosed, sometimes open on one side. In fortification, *corridor* signifies the same as *covert-way*.

Corrosives, in *surgery*, are medicines which corrode whatever part of the body they are applied to; such are burnt alum, white precipitate of mercury, white vitriol, red precipitate of mercury, butter of antimony, lapis infernalis, &c.

Corrosive Sublimate. See Mercury.

Corset; an article of dress, especially intended to preserve or display the beauties of the female form. Its name appears to have been derived from its peculiar action of tightening or compressing the body, and may be compounded of the French words *corps* and *serrer*. To prevent the form from too early showing the inroads of time; to guard it from slight inelegances, resulting from improper position, or the character of exterior drapery; to secure the proportions of the bust from compression or displacement; and, at once, agreeably to display the general contour of the figure, without impeding the gracefulness of its motions, or the gentle undulations caused by natural respiration, are the legitimate objects of the corset. For this purpose, it should be composed of the smoothest and most elastic materials, should be accurately adapted to the individual wearer, so that no point may receive undue pressure, and should never be drawn so tight as to interfere with perfectly free breathing, or with graceful attitudes and movements.

If, however, it be remembered that the use of corsets is to preserve and display a fine figure, not to *make* one, and that they are to be secondary to a judicious course of diet and exercise, it will be readily perceived that any injurious agents are utterly uncalled for in their composition. By selecting a material proportioned, in its thickness and elasticity, to the size, age, &c., of the wearer, and by a proper employment of quilting and wadding, they may be made of any proper or allowable degree of stiffness. If it be then accurately fitted to the shape of the individual, and laced no tighter than to apply it comfortably, all the advantages of the corset may be fully obtained. But such, unfortunately, is not the course generally pursued. Ladies purchase corsets of the most fashionable makers, and of the most fashionable patterns and materials, regardless of the peculiarities of their own figures, which may require a construction and material of very different description. As no two human figures are precisely alike, it is absolutely requisite that the corset should be suited with the minutest accuracy to the wearer; and a naturally good figure cannot derive advantage from any corset but one constructed and adapted in the manner above indicated. Slight irregularities or defects may be remedied or rendered inconspicuous, by judicious application of wadding, or by interposing an additional thickness of the cloth. But it should be remembered that certain changes occur to the female frame, after the cares of maternity have commenced, which are absolutely unavoidable. Among these, the general enlargement or filling up of the figure is the most observable, but is never productive of inelegance, unless it takes place very disproportionately. The undue enlargement of the bust and waist is most dreaded, and the attempt to restrain their developement by mere force has led to the most pernicious abuse of the corset. There is no doubt but that a judiciously fitted corset, whose object should be to support and gently compress, might, in such cases, be advantageously worn; but, at the same time, it must be thoroughly understood, that the corset can only be really beneficial when combined with a proper attention to diet and exercise.

Thus many ladies, who dread the disfigurement produced by obesity, and constantly wear the most unyielding and uncomfortable corsets, lead an en-

tirely inactive life, and indulge in rich and luxurious food. Under such circumstances, it is vain to hope that beauty of figure can be maintained by corsets, or that they can effect any other purpose than that of cramping and restraining the movements, and causing discomfort to the wearer. On the other hand, proper exercise, and abstinence from all but the simplest food, would enable the corset to perform its part to the greatest advantage. There is another error, in relation to corsets, as prejudicial as it is general, and calling for the serious attention of all those concerned in the education of young ladies. This error is the belief that girls, just approaching their majority should be constantly kept under the influence of corsets, in order to *form* their figures. They are, therefore, subjected to a discipline of strict lacing, at a period when, of all others, its tendency is to produce the most extensive mischief. At this time, all the organs of the body are in a state of energetic augmentation; and interference with the proper expansion of any one set is productive of permanent injury to the whole. So far from making a fine form, the tendency is directly the reverse, since the restraint of the corsets detrimentally interferes with the perfection of the frame. The muscles, being compressed and held inactive, neither acquire their due size nor strength; and a stiff, awkward carriage, with a thin, flat, ungraceful, inelegant person, is the too frequent result of such injudicious treatment.

We may conclude what we have to say on the use of the corset, by embodying the whole in a few plain general rules:—1st. Corsets should be made of smooth, soft, elastic materials. 2d. They should be accurately fitted and modified to suit the peculiarities of figure of each wearer. 3d. No other stiffening should be used but that of quilting or padding; the bones, steel, &c., should be left to the deformed or diseased, for whom they were originally intended. 4th. Corsets should never be drawn so tight as to impede regular, natural breathing, as, under all circumstances, the improvement of figure is insufficient to compensate for the air of awkward restraint caused by such lacing. 5th. They should never be worn, either loosely or tightly, during the hours appropriated to sleep, as, by impeding respiration, and accumulating the heat of the system improperly, they invariably injure. 6th. The corset for young persons should be of the simplest character, and worn in the lightest and easiest manner, allowing their lungs full play, and giving the form its fullest opportunity for expansion.

Corvette; a vessel of war having fewer than 20 guns.

Costume, in the *fine arts;* the observance of propriety in regard to the person or thing represented, so that the scene of action, the habits, arms, proportions, &c., are properly imitated. The peculiarities of form, physiognomy, complexion, the dress, ornaments, habitations, furniture, arms, &c., should all be conformable to the period and country in which the scene is laid. The rules of costume would be violated by the introduction of a palm-grove and a tiger in a scene in Russia, by the representation of American Indians in turbans, or of Romans with cannons at the siege of Carthage, or an inhabitant of the East seated at table with a knive and fork.

That the ancient painters, and even celebrated masters of the modern European schools, are often chargeable with deviations from propriety in regard to costume, is not to be denied; but nowhere have they been so glaring as on the stage, where Greek, Turkish and Peruvian princes used to make their appearance in long velvet mantles, embroidered with gold; Merope and Cleopatra were equipped in hoop-petticoats, Medea and Phædra in French head-dresses; peasant-girls were dressed out in whalebone, and heroes emerged from the battle in stiff coats, not a fold of which was disordered. Le Kain and Mademoiselle Clairon, it is said, were the first who introduced propriety of costume on the stage, under the patronage of the Count de Lauraguais; but they excluded only the grosser absurdities; Scythians and Sarmatians were clothed in tiger-skins, Asiatics in the Turkish dress; but the old costume was retained in other respects. The scenery of the stage was as incongruous as the dresses.

It is not long since Semiramis issued from a palace adorned with Corinthian columns, and entered a garden in which a whole American Flora was blooming; or perhaps she was seated on a throne, overshadowed with a canopy *à la Polonaise*. Those by whom she was surrounded were dressed in the Turkish style; while a master of horse, in the costume of the age of chivalry, offered her his hand. In Germany, the stage at that time, was no better in this respect. It is not very long since the companions of Theseus made their appearance there with large perukes; and, in the *Clemenza di Tito*, Roman soldiers marched on the stage with stiff boots, and stiffer queues. The Germans, however, first made a thorough reform in these absurdities, and the national, now royal, theatre, in Berlin, in point of scenery and costume, is at present one of the most correct in the world. In France, Talma reformed the Parisian stage. What he did in this respect for the drama, David (who had, however, a predecessor in Vienna) effected for painting, and his school is entitled to the honour of having strictly observed propriety of costume. In England, also, a most praiseworthy attention is now paid to propriety in dramatic costume, especially at the Theatre Royal, Covent Garden, where Mr. J. P. Kemble set a noble example of accuracy and splendour in the dresses and decorations, which he had made for the first production of the historical plays of Shakspeare, in the new house. Since his time, the same laudable path has been trodden by the proprietors and managers of that establishment, under the direction of Mr. J. R. Planché and others, with all the advantages which extended research and new sources of information can impart to the subject.

There is often no means of information for the artist but the original sources. For the costume of the ancients, he must have recourse to the engravings of antiquities; for the modern costume, he must resort to essays on painting in different ages, monumental figures, and treatises on costume; and in regard to the costume of foreign nations, he may derive information from books of travels; histories, antiquities and geographies, are indispensable guides in these inquiries. All the important peculiarities of foreign costume will be found depicted in the geographical division of this work.

Cotton is a soft, vegetable down, which is contained in the seed-vessels, and envelopes the seeds, of the cotton plant, which is cultivated in the East and West Indies, North and South America, and Egypt; in fact, in most parts of the world which possess a

sufficiently warm climate. The cotton-pods are of somewhat triangular shape, and have each three cells. These, when ripe, burst open, and disclose their snow-white or yellowish contents, in the midst of which are contained the seeds, in shape somewhat resembling those of grapes. The fibres of cotton are extremely fine, delicate, and flexile. When examined by the microscope, they are found to be somewhat flat, and two-edged or triangular. Their direction is not strait, but contorted, so that the locks can be extended or drawn out without doing violence to the fibres. These threads are finely toothed, which explains the cause of their adhering together with greater facility than those of bombax and several *apocyneæ*, which are destitute of teeth, and which cannot be spun into thread without an admixture of cotton.

The increase of the cotton manufacture, during the last half century, is one of the most interesting events in the history of commerce. The earliest seat of the manufacture, known to us, was Hindostan, where it continues to be carried on, by hand labour, in all its original simplicity.

Those who have seen the wonderful powers exhibited by the machinery of Hargraves and Arkwright, would scarcely conceive the process still employed in our own eastern possessions; and nothing but the jealousy of the British governors in the East could have so completely retarded the progress of improvement as is the case through the whole of Hindostan. We give an engraving of this primeval process, originally copied from a curious Hindoo MS.

Such has been the power of improved machinery, in its recent application to the spinning of cotton and its general manufacture, that Great Britain and America are now pouring back upon Asia her original manufacture, and underselling her in her own markets. The first impulse in these improvements was derived from the inventions of Hargraves and Arkwright, between 1767 and 1780.

The improved machinery of which we speak consists of the cylindrical carding engine, by which the fibres of cotton are disentangled and separated from each other, and from all foreign substances, and delivered in a uniform, continuous roll; the drawing and roving frames, by which these rolls are repeatedly doubled and extended, until the fibres are drawn out in a regular and perfectly horizontal position; and the spinning frame, the most important quality of which is the causing the roving or preparatory yarn to pass through two or more sets of rollers, revolving with different velocities, by which the thread, at the moment of being twisted, is drawn out to any desired degree of tenuity; the rollers performing the delicate office of the thumb and finger. In addition to these, the power-loom was brought into general use about the year 1816, by which the laborious process of weaving is converted into the mere superintendence of two, and even three, of these machines; each one producing from 30 to 40 yards of cloth per day. In the printing of calicoes, equally important improvements have been made.

Instead of the tedious process of impressing patterns from wooden blocks, the most delicate patterns are transferred from copper cylinders with astonishing rapidity; two, and even three, colours are, in this way, imprinted at one operation. In the richer and more expensive patterns, however, block-printing continues to be used, in addition to the impressions from the cylinders. The science of chemistry has contributed its share of improvement in the new process of bleaching by chlorine, and in innumerable new combinations of colours. In its present state, the entire manufacture, in its various departments, presents a greater combination of human skill than can be found in any other art or manufacture.

In 1781, the quantity of cotton wool imported into Great Britain was upwards of 5,000,000lbs; in 1829, it exceeded 218,000,000; and, allowing 20,000,000 for export, 190,000,000 pounds will remain as the consumption of the kingdom. Of this, upwards of 40,000,000 pounds are exported in yarns, valued at 3,500,000*l*. sterling. The value of other manufactures of cotton, exported in 1828, was 13,545,638*l*. The most probable estimate of the annual value of the cotton manufactured in Great Britain is 36,000,000*l*. sterling.

In the early periods of this manufacture, the profits must have been enormous. It has built up the cities of Liverpool and Manchester, of Glasgow and Paisley, and has been estimated to give employment to a million of persons. After a long period of success, interrupted only by occasional and temporary fluctuations, the production, both of the raw material, and of the manufactured article, seems to have outrun the consumption of the world, in that eventful year of overtrade, 1825. A long stagnation succeeded in 1826; an unprecedented reduction in the prices of cotton manufactures, and in the value of property engaged in it, spread a wide and general distress, throughout the districts devoted to this manufacture, which continued, with greater or less intensity, through the years 1828 and 1829.

Although there is no diminution in the quantity of cotton consumed in Great Britain, there is abundant evidence, that neither the capital nor labour employed in it is now receiving a fair remuneration. The fall in the prices of cotton manufactures, from 1814 to 1826, would seem, by a comparison of the real or declared value of the exports with the official value, rated by a uniform list, to have been 55 per cent. The greatest export in value, of any one year, up to 1815, having exceeded 19,000,000*l*. sterling.

We annex an important official document, which will best show the value of the cotton trade to Great Britain:—

Account of the Export of Cotton Goods and Yarn in 1829; *specifying the countries to which they were sent, and the quantity and value of those sent to each.*

Countries to which Cotton is Exported.	Cotton Manufactures.			Cotton Twist and Yarn.

For a full account of the mechanical processes, see SPINNING, WEAVING, &c.

COUCHANT; an heraldic term to express an animal lying close to the ground, having the head erect in order to distinguish him from an animal *dormant*.

COUCHING, in *surgery;* an operation that consists in removing the opaque lens out of the axis of vision, by means of a needle constructed for the purpose of effecting that object.

COUGH, in *medicine;* a deep inspiration of air, followed by a sudden, violent, and sonorous expiration, in a great measure involuntary, and excited by a sensation of the presence of some irritating cause in the lungs or windpipe. The organs of respiration are so constructed, that every foreign substance, except atmospheric air, offends them. The smallest drop of water, entering the windpipe, is sufficient to produce a violent coughing, by which the organs labour to expel the irritating substance. A similar effect is produced by inhaling smoke, dust, &c. The sudden expulsion of air from the lungs is produced by the violent contraction of the diaphragm and the muscles of the breast and ribs. These parts are thus affected by a sympathy with the organs of respiration, which sympathy springs from the connection of the nerves of the different parts.

The sensation of obstruction or irritation, which gives rise to cough, though sometimes perceived in the chest, especially near the pit of the stomach, is most commonly confined to the *trachea*, or windpipe, and especially to its aperture in the throat, termed the *glottis*. Yet this is seldom the seat of the irritating cause, which is generally situated at some distance from it, and often in parts unconnected by structure or proximity with the organs of respiration. Of the various irritations which give rise to cough, some occur within the cavity of the chest; others are external to that cavity; some exist even in the viscera of the pelvis. Of those causes of cough which take place within the chest, the disorders of the lungs themselves are the most common, especially the inflammation of the mucous membranes, which excites the catarrhal cough, or common cold. This disease is generally considered unimportant, particularly if there be no fever connected with it. But every cough, lasting longer than a fortnight or three weeks, is suspicious, and ought to be medically treated. Another common cause of cough, which has its seat in the lungs, is inflammation of those organs, whether in the form of pleurisy or peripneumony.

These diseases do not differ very essentially, except in violence and extent, from the acute catarrh, but are more dangerous, and more rapid in their progress, and the constitution is excited to a highly febrile condition. Even after the acute state of inflammation may have subsided, a cough, attended with extreme danger, sometimes continues to be excited by collections of pus, or abcesses, which ensue in the substance of the lungs, and either terminate in consumption, or suffocate the patient by suddenly bursting; more rarely the pus is discharged gradually from a small aperture, and the patient recovers. In such cases, the fever, originally acute, is converted into a hectic, with daily chills, succeeded by heat and flushing of the face, night sweats, and emaciation.

Another frequent origin of cough is the rupture of some of the blood-vessels of the lungs, and the consequent effusion of blood into the cells, which is expelled by the cough that its irritation excites, constituting what is technically termed *hæmoptoe, hæmoptysis*, or spitting of blood. When the vessels of the lungs are thus ruptured, they seldom heal readily, but degenerate into ulcers, which pour out a purulent matter; and, by this discharge, the vital powers are gradually worn down and destroyed. This is a common source of consumption, or *phtisis pulmonalis*.

A cough is excited, and the same fatal disorder is also induced, by the existence of tubercles in the lungs. These are little tumours, which gradually inflame and ulcerate, and produce the same consequences as the ulcerations from *hæmoptysis*. *Calculi*, or stony concretions, are sometimes formed in the lungs, and the irritation which they produce necessarily excites a cough, which is liable to terminate in consumption. There is yet another source of irritation within the lungs, of which cough is an attendant, namely, an effusion of *serum*, into the parenchymatous substance of the lungs, or into the cellular membrane, which connects the cells and blood-vessels together. This has been called *anasarca pulmonum*, or dropsy of the lungs, and is marked by great difficulty of breathing, with a sense of weight and oppression in the chest, occasioned by the compression of the air-cells and vessels by the accumulated water; hence also great irregularity of pulse, frightful dreams, imperfect sleep, &c., are among its symptoms.

Inflammation of the heart, and of the *pericardium*, or membrane surrounding it, is also accompanied by cough, and other symptoms not easily distinguishable from those of pleurisy and peripneumony. Where a cough is excited by disorders of parts external to the cavity of the chest, it is generally dry, as the irritating cause is external, and not any obstructing matter in the lungs themselves. Disorders of the viscera of the abdomen, especially of those which lie in contact with the diaphragm (the muscular curtain separating the cavities of the belly and chest), frequently induce a cough.

A short, dry cough invariably attends inflammation of the liver, whether acute or chronic, and accompanies the various tubercular and other obstructions in that organ. Hence inflammation of the liver is not unfrequently mistaken for inflammation of the lungs; and, in some of the chronic disorders of the liver, the cough is occasionally complained of as the most urgent symptom. The presence of pain in the right side, shooting up to the top of the shoulder, the dryness of the cough, and pain, enlargement, hardness, or uneasiness on pressure below the ribs of that side, will afford the best means of distinguishing whether a disease of the liver is the origin of the cough.

Disorders of the stomach are, also, often accompanied with a cough of the same dry and teasing nature, especially when that organ is over distended with food, or is in the opposite condition of emptiness. A short cough is, therefore, a frequent symptom of indigestion and hypocondriasis, or of that weakness of the stomach which is popularly termed *bilious*. In short, there is scarcely any one of the viscera, in the cavity of the abdomen, the irritation of which, in a state of disease, has not excited cough. Disorders of the spleen, pancreas, and even the kidneys, have all given rise to this symptom; and external tumours attached to them, have had the same effect. Any distention of the abdomen, which, by

its pressure upwards, impedes the descent of the diaphragm, and consequently the expansion of the lungs, occasions cough. Thus, in the *ascites*, or dropsy of the belly, the water—in tympanites, the air—in corpulency, the fat in the omentum—and, in pregnancy, the gravid uterus,—all have the effect of exciting cough in many constitutions. The variety of causes from which coughs may arise, must convince every reader of the absurdity of attempting to cure all kinds of cough by the same remedy.

Course, in *navigation;* that point of the compass or horizon on which the ship steers.

Course, in *architecture;* a continued range of bricks or stones, level or of the same height throughout the length of a whole building, without being interrupted by any apparent aperture.

Counterguards, in *fortification*, are small ramparts with parapets and ditches, to cover some part of the body of a place. They are of several shapes, and differently situated. They are generally made before the bastion, in order to cover the opposite flanks from being seen from the covert-way, and, in this case, consist of two faces, making a salient angle parallel to the faces of the bastion. They are sometimes made before the ravelins. The cost of building them is more than proportionate to their value, especially when they are small, and without cannon, in which case, particularly, they are called *couvrefaces*.

Countermark, in *numismatics*. Antiquaries call by this name those stamps or impressions which are found on ancient coins or medals, and have been given since their first impress in the mint. These countermarks or stamps are often executed without any care, and frequently obliterate the most interesting portion of the original inscription. Thus they correspond with the *codices rescripti*. In performing this operation, the new mark was stamped upon the coin with a heavy blow of a mallet upon a punch, on which was engraved the countermark, of a round, oval, or square shape. The use of countermarks appears to have been first adopted by the Greeks, but it is impossible to say at what period of their history. Upon the Greek coins so altered, the countermarks are generally figures, accompanied by inscriptions. Those of Rome seldom contain any thing more than inscriptions and monograms.

There have been various opinions respecting the cause of these countermarks; some antiquaries thinking that they were to indicate an augmentation of the value of the money upon which they were stamped; others, that they were vouchers for workmen; and, again that they were only struck upon money taken or received from foreign enemies. Jobert, Millin, De Boze, Bimard, Mabudel, Pelleim, Florez, and other antiquaries, have exercised their conjectural skill on this subject. During the long war with revolutionary France, England stamped millions of Spanish dollars with small, oval countermarks of the head of George III. upon the neck of the Spanish monarch. Many of them were completely restamped or countermarked in the mint, and both impressions were sometimes visible, the English head and reverse not completely destroying the Spanish head, armorial bearings, and inscriptions.

Counterpoint signifies, in *music*, a part or parts added to a given melody. In ancient times, musical sounds were represented by certain letters of the alphabet. A great improvement was made on the old system by the celebrated Guido d'Arezzo, who substituted points or dots in the place of letters. The simple harmony of that period consisted of notes equal in length, and the term *contrapunctus*, or *counterpoint* was applied to it in consequence of the points by which it was represented being placed under, or, as it were, against each other, on the staff. By *counterpoint*, we understand, therefore, the several parts which compose musical harmony; and the science of counterpoint consists in a knowledge of the rules according to which those parts must be constructed. On this account, the term is fequently used for musical composition in general. When the notes employed are of equal length, the counterpoint is called *simple*. When notes of various length are used, the counterpoint is said to be *figurate* or *florid*.

Counterpointed, in *heraldry*, is when two cheverons in one escutcheon meet in the points, the one rising as usual from the base, and the other inverted falling from the chief, so that they are counter to one another in the the points. They may also be counterpointed when they are founded upon the sides of the shield and the points meet that way, called counterpointed in fesse.

Counterpoise, in *mechanics;* a weight standing in opposition to another weight. Thus when a weight is placed on each side of a beam, so that neither of the two preponderates, each weight is said to be a counterpoise to each other.

Counterproof, in *engraving;* an impression taken from a newly-printed proof of a copperplate, for the purpose of a closer investigation of the state of the plate, as the proof is, in every respect, the reverse of the plate, while the counterproof has everything the same way.

Counter Salient, in *heraldry*, is when two lions are borne in a coat, leaping from each other, directly in the contrary way.

Counterscarp, in *fortification*, is properly the slope or *talus* of the exterior side of a ditch, towards the field. The inner slope, on the side towards the place, is called *escarpe*. Sometimes the covert-way and glacis are termed *counterscarp*.

Coup. This term is used in various connections, to convey the idea of promptness and force. *Coup de main*, in military language, signifies a prompt, vigorous, and successful attack. *Coup d'œil*, in a military sense, a rapid conception of the advantages and weaknesses of positions and arrangements of troops. It is also used for a quick comprehension of all the points and bearings of any subject. *Coup de théâtre*, a sudden and striking change in the action. *Coup d'état* is a forcible and arbitrary political measure.

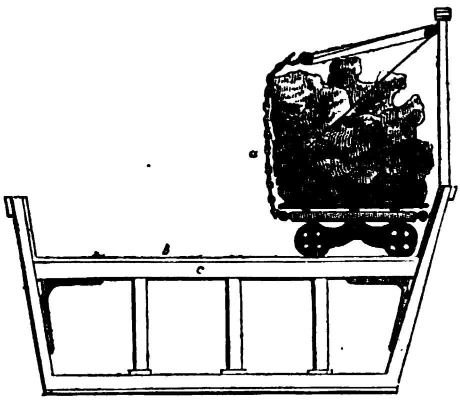
Coupurus, in *fortification*, are passages sometimes cut through the glacis, of about twelve or fifteen feet broad, in the re-entering angle of the covert-way, to facilitate the sallies of the besieged. They are sometimes made through the lower curtain, to let boats into a little haven, built on the re-entering angle of the counterscarp of the out-works.

Covered-Way; a space of ground on the edge of the ditch, ranging round the works of a fortification. Its glacis descends by an easy slope, towards the field. It affords a safe communication round all the works, facilitates sallies and retreats, and the reception of auxiliaries, compels the enemy to begin his operations at a distance, checks his approach and the erection of

breach batteries, and its parapet protects the fortifications in its rear.

Cowry-Shells; shells used for coin; a kind of small muscles, belonging to the Indian seas, &c.— The largest are an inch and a half in size, and indented on both sides of the opening. They are collected twice a year in the bay of Bengal, on the Malabar coast, and, in still greater quantity, in the neighbourhood of the Maldive islands. They are used throughout the East Indies, especially in Bengal and in the African trade, instead of small coins. The demand is so great, that, notwithstanding the insignificant price (in 1780, a pound of them might be bought for three cents), about 150,000 dollars worth are sent every year to Bengal.

Crab, in *ship-building;* a very common substitute for the capstan. We notice this mechanical arrangement, to describe one which was employed in the erection of the Breakwater at Plymouth: it is represented beneath.



A strong flat-bottomed vessel furnished with a deck, at *c*, of which we show a section, was employed for the transport of stones from the quarry to the site of the work. The carriage with the block was then rolled along the line *b*, to the side of the vessel; the chain *a*, raised by the blocks above, and when it attained a certain angle, precipitated into the sea.— The stones deposited by this means exceeded five tons in weight. Of this gigantic work we shall give a full account under Plymouth, in the Second Division of this work.

Cradle, in *ship-building;* a frame placed under the bottom of a ship, in order to conduct her, smoothly and steadily into the water, when she is launched; at which time it supports her weight whilst she slides down the descent or sloping passage called the *ways*, which, to facilitate her passage, are coated with soap and tallow.

Craft, in sea language, signifies all manner of nets, lines, hooks, &c. used in fishing. Hence little vessels, as ketches, hoys, smacks, &c., of the kind commonly used in the fishing trade, are called *small craft.*

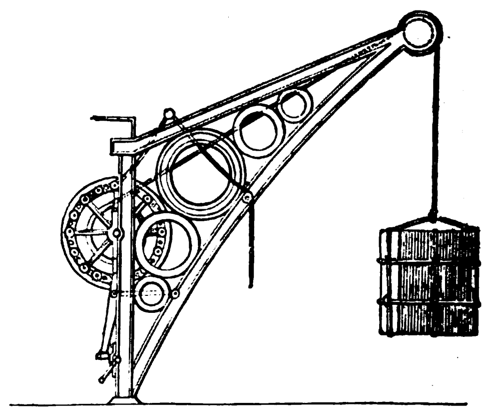
Cramp, in *architecture* and *sculpture;* pieces of iron, bronze, or other metal, bent at each end, by which stones in buildings, and limbs, &c., of statues, are held together. The ancient Romans made great use of cramps in their buildings, and the cupidity of modern barbarians, like Pope Barberini, has destroyed many a fine work for the sake of the bronze used in its construction. The Pantheon, with its fine portico, by Agrippa, and the Coliseum have suffered most from these wanton aggressions, and the baldachin of St. Peter's, and some eighty pieces of brass ordnance, are nearly all that we have in exchange for some of the finest works of which the world could boast.

Cramp, in *medicine*. See Spasm.

Crane, in *mechanics;* a very useful instrument for raising great weights. A crane usually consists of a jib or projecting lever, furnished with two pulleys, round which a rope or chain is coiled, so that while the weight to be raised is attached to one end of the cord, the other passing over a second pulley, descends to a wheel and axle to which animal power is applied.

Cranes thus constructed are found at the large warehouses in which heavy goods are deposited. Even this species of instrument might, however, be rendered much more useful than it now is, by attaching it to the large luggage carts used in the metropolis, instead of trusting to the remote contingency of finding the apparatus in order at the retail shopkeepers where parcels are delivered. The streets would not in that case be impeded as they now are by temporary inclined planes and large barrels, which block up the foot-path.

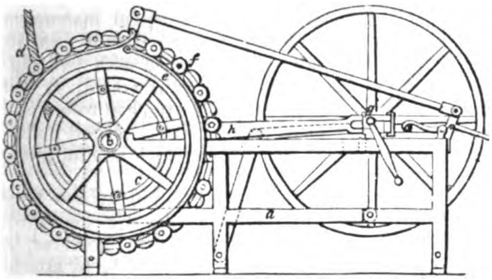
We may now notice a very great improvement on the crane, by Mr. Wright, which materially diminishes the labour of those employed. A view of the machine is given in the engraving beneath.



This crane consists of a novel combination of mechanical powers, constructed without either toothed wheel or pinion, its whole power being derived from a peculiar adaptation of the lever and wedge. These are made to act on rollers, mounted on wheels, which are attached to the drum or barrel that the draft-rope or chain winds upon.

Before we examine the working part of the chain, it may be proper to say, that that part of the patent which relates to the employment of compressed air as a substitute for the labour of men, is of no practical utility, and altogether as fallacious as the crane itself is ingenious. In the section on the accompanying page, *a* represents the side standard which supports the pivot, *b*, of the barrel or drum, *c*, round which the draf-trope or chain, *d*, is wound; *e* is a wheel or circular rim affixed to the axle of the drum. This rim carries a series of friction rollers, *f*, &c. mounted on pins, projecting

alternately from each side of the wheel. A four-throw crank, *g*, turns in a swinging frame; and to each of the cranks is attached a lever as at *h*, with a wedge-formed end which acts on the rollers. At one end of the crank shaft is a fly-wheel, to regulate the motion of the machine.



On the power being applied to the cranks, *g*, by the winch handles, or by any other means, the cranks as they revolve towards the drum wheels project forward; the levers and their wedge-formed ends successively pass under and raise the rollers, and when past their centres revolving from the drum wheels the cranks depress the longer arms of the levers, and raise the shorter arms with the rollers, and thus successively drive round the rims, and with them the drum or barrel.

To throw the machine out of gear, the ends of the levers must be withdrawn from the friction rollers; to do this, the pauls must be removed from supporting or wedging up the back of the swinging frame, by lifting up the handle on the shaft, when the frame with the crank shaft and levers may be drawn back against a rest.

The crank and levers being thus out of gear, the barrel is at liberty to turn the reverse way, for the purpose of lowering the weight suspended, and the velocity of the descent is to be regulated by a two-part break, as shown in our first figure.

When it is required to put the machine into action, the counter-balance weight hung over the pulley by a chain or rope from the swinging frame, will assist to bring the swinging frame up into its working position, when the pauls will fall down.

The following experiment was made with this crane in a large establishment before the Editor of the *London Journal of Science*:—

A common crane was worked by six men, accustomed to the work, while Mr. Wright's crane was worked by three bricklayer's labourers taken from the hod, and yet with these enormous disadvantages, as to strength and habit, the comparative work of the two cranes was very much in favour of Mr. Wright's new construction.

The weight raised by each crane and each set of men was 18 cwt.; and the space through which it was raised each time 30 feet.

The six men, with the common crane, worked 2 hours 23 minutes and 36 seconds, and hoisted the weight 81 times; being on an average once in every minute 46 seconds and four-tenths of a second.

The three men with Mr. Wright's crane, worked only 2 hours 10 minutes and 30 seconds (an accidental fracture of part of his machine causing it to stop sooner than the other), and hoisted the weight 46 times, being on an average once in every two minutes 50 seconds and two-tenths of a second.

To reduce the work done by the two sets of men to equal terms of comparison, we must,

First, equalize the time occupied:

	h.	m.	sec.
The six men worked	2	23	36
The three	2	10	30
Difference . .		13	6

So that we must deduct from the total number of hoists (81) made by the six men, the number of hoists in 13 minutes 6 seconds, which, at one hoist per minute 46 seconds and four-tenths, is nearly 8; say, however, only 7; this reduces the actual number of hoists made by the six men in the same space of time to 74.

Secondly, we must equalize the manual power employed; to do which we must take half only of the work done by the six men, or 37.

We have, then, for the work done in 2 hours 10 minutes 30 seconds, by three men, with the old crane 37

By three men, in the same time, with Mr. Wright's crane 46

Gain by the new crane . 9

The result of this experiment gives an advantage in favour of the new crane, of nearly one-fourth.

Cranium. A portion of the bony frame-work of the head is divided into the cranium proper or brain case, and the face.

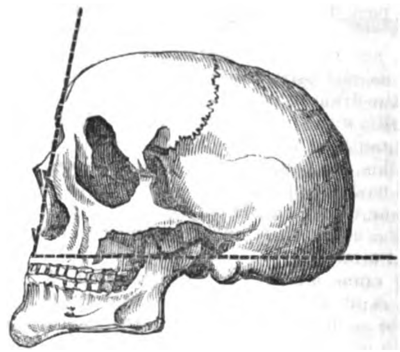
The bones of the cranium are composed of two compact plates called *tables*, an external, and an internal or vitreous table with an intervening loose bony structure called *diploë*,—a distinction which is not evident at the thinner parts of the bones, and which does not exist in the young subject or in the face. There is a considerable variation in the thickness and density of the skull. both in different parts and in various individuals; its inner surface is marked by the impressions of the brain which is most apparent at the base; there are also pits for the lodgment of glands and grooves, and canals for the passage of blood-vessels.

The cranium proper is composed of eight bones; viz. The occipital bone, 2 parietal bones, 2 temporal bones, the frontal, the sphenoid and the æthmoid bones, the three latter being common to the skull and face. The bones of the face are distributed into two divisions,—those of the upper jaw, and a single bone for the lower, the inferior maxillary bone: the upper jaw consists of six bones on each side, and one bone in the centre, making thirteen; viz., 2 nasal, 2 lachrymal, 2 malar, 2 superior maxillary, 2 palate, 2 inferior spongy bones, and the single bone called vomer from its resemblance to a ploughshare. The various bones of which the head is composed are connected by an immoveable species of articulation called *suture* (from the Latin word for *sewing*, *sutura*), which, when the soft structures are removed still retains the bones in apposition. These sutures are of three kinds,—1. The true or serrated suture, produced by numerous small processes of one bone being received into corresponding cavities of the opposed edge of another. 2. The squamous suture, where

one bone overlaps the other like the scales of a fish. 3. Harmonia or union by plain surfaces, by which suture principally the bones of the face are connected. The mode in which the teeth are implanted in their sockets is termed *gomphosis* from its *nail*-like character. Separate pieces of bone, varying in size and form, are found in the course of the sutures, and are called *ossa triquetra*, or *wormiana*. The sutures of the cranium proper are, the coronal, the sagittal, the lambdoidal, the 2 squamous sutures, the 2 additamenta suturæ squamosæ, and the 2 additamenta suturæ lambdoidalis. The sutures common to the cranium and face are, the transverse orbitar, the spheroidal, the æthmoidal, and the 2 zygomatic sutures. The sutures proper to the face are, the anterior nasal, the 2 lateral nasal, the 2 palato-maxillary, the 2 external and 2 internal orbitar, the longitudinal palate, the transverse palate, the spinous, the mystachial, and the 2 lachrymal sutures.

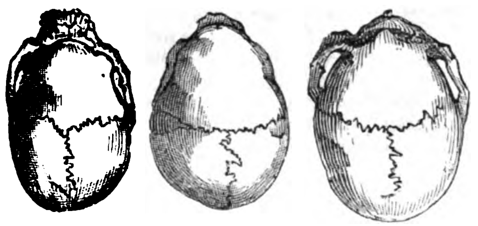
The bones, when connected form a cavity, or brain-case for the reception and protection of the brain; and as the skull is composed of an outer, tough, and fibrous, and an inner, brittle, or glassy table, we see a beautiful provision to avert the injurious effects of a jar or concussion of the brain from a blow or fall; the skilful adjustment of the bones by the serrated suture or dovetailing, and the overlaping of one bone over another, are also mechanical contrivances admirably adapted by infinite wisdom to give strength and stability to the cranial arch. At birth, the bones are in but an imperfect state, ossification is proceeding, having commenced at numerous central points and radiating towards the circumference: at the junction of the two parietal bones with the frontal, so great a membraneous space is left, that the pulsation communicated to the brain by its vessels can be felt, and this is called the *anterior fontanelle* or *bregma*, while a smaller space between the two parietal bones and the occipital is termed the *posterior fontanelle*. The frontal bone early in life consists of two portions united by a continuation of the sagittal suture, which at the adult period is generally, but not always, obliterated. Dr. Leach, who examined the immense collection of crania in the catacombs at Paris, remarked that the frontal suture remained unobliterated in about one out of eleven crania; and a similar observation respecting the frequency of crania with this suture unobliterated in the cemetery at Hythe, has induced the inference that they are Norman. The greatest diameter of the cranium is from the forehead to the occiput, and measures 6½ inches; the greatest transverse diameter is 5½ inches; the greatest perpendicular, 5 inches. The exterior of the skull is smooth and uniform, and does not generally correspond with the eminences and depressions made by the convolutions of the brain on the internal surface; the base however is irregular, and has numerous holes for the passage of vessels and the nerves proceeding from the brain. On each side of the skull is observed a remarkable hollow, called the *temporal fossa*, filled up in the recent state by the temporal muscle which closes the lower jaw. The bones of the face contribute principally to form the cavities of the orbit, nose, and mouth. The orbitar cavities are formed each by seven bones,—the frontal, sphenoid, æthmoid, superior maxillary, malar, lachrymal, and palate bones; they are of a square form, and in order to command a more extensive field for vision, face rather outwards. The bones of the nose are of a light thin texture, arranged so as to afford an extended surface for the olfactory membrane, and consist of all the bones of the face, with the exception of the two malar bones. The two superior maxillary bones have 16 *alveoli* or sockets, for the reception of the teeth of the upper jaw, while the inferior maxillary bone has the same number of sockets for the teeth of the lower jaw.

Observing the varying forms of the head and features, which not merely characterise distinct races of mankind, but are sufficiently striking even in individuals of the same nation, it is obvious that these peculiar conformations must essentially depend on the configuration of the bones of the head; accordingly, in comparing the crania of individuals of different nations, we find the national peculiarities as uniform as the colour of the skin and other distinctive characters. This interesting subject was however little attended to by anatomists until Camper ingeniously attempted by his *facial angle* to distinguish not only the crania of the human species, but to mark out the diversities of the animal kingdom, by establishing a scale ascending from animals of an inferior garde to the most beautiful and perfect specimens of the human cranium.



The cranium being viewed in profile, two imaginary lines must be drawn, one proceeding horizontally through the meatus auditorius externus and the floor of the nostrils, the other passing from the prominent part of the forehead to the alveolar projection of the upper jaw; thus, the angle formed by the junction of the two lines will be smallest in birds, in the monkey 42°, in the African Negro 70°, in the European 80° The ancients in the statues of their heroes and great characters, have made the facial angle 90°, while, to express the sublime majesty of a heathen god, it is increased to 100°. Considering therefore the relative proportions of the cranium and face in a vertical section of the head made longitudinally, the area of the cranium of the European is four times as large as that of the face; in the monkey they are about equal; whereas in ruminating animals the area of the face is about double that of the cranium. In applying the facial angle of Camper, the calculation is obscure and uncertain, it neither affords a correct estimate of the human intellect, as dependant upon the developement of the brain, nor furnishes a measure of the proportions in which animals are endowed with sagacity. As a means of distinguishing national variations in the conformation of the skull, it is objected, that it only indicates those va-

rieties of form which depend on the prominence and figure of the forehead and upper jaw, and gives no intimation of the breadth of the face or of any other peculiarities in the shape of the skull. Blumenbach possessing an extensive collection of crania of different nations, was able to make many important observations, and by remarking the variations in the breadth of the skulls of the inhabitants of different countries, and other striking differences in their configuration has arranged crania into five classes. The skulls must be placed in a line upon a table with their zygomas touching, and then viewed from behind, the eye being fixed on the vertex of each, so as to observe the variations in their shapes; this is termed the *vertical method*. The three classes most remarkably distinguished from each other are the *Caucasian*, *Mongolian*, and *Æthiopian*.

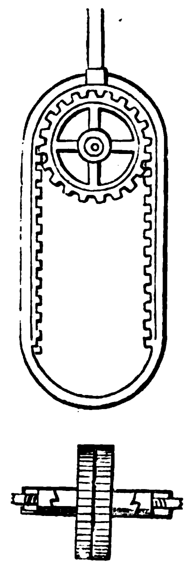


The central one, or Caucasian, includes the nations of Europe, the Western Asiatics, and the Northern Africans. Shape of the head, symmetrical—forehead well developed, concealing the face—face narrow—cheek-bones not projecting—chin full and round. Mongolian, or right hand figure, includes the Asiatics not comprehended in the first division, and the inhabitants of the northern parts of Europe and America. Head almost square—face broad—cheek-bones projecting outwards—nose flat—chin prominent. The Æthiopians, or extreme left, comprehends all the Africans not included in the first division. Head narrow, compressed at the sides—forehead convex—cheek-bones projecting forwards—jaws lengthened—front teeth projecting—large nasal cavity. The fourth, or American, including all the Americans except the inhabitants of the northern parts, may be placed between the Caucasian and the Mongolian. Cheek-bones prominent—forehead small and low—orbits deep—nasal cavity large. The last class, or Malay, being an intermediate link between the Caucasian and Æthiopian, comprehends the inhabitants of the numerous Asiatic islands, and those of the Great Pacific Ocean. Cranium narrow, and slanting at its upper and front part—face large—jaws prominent. Under this classification the crania of the various tribes of the human race may be arranged, with some exceptions.

The peculiarity in the configuration of the skull of some nations is not always natural, the most striking instance of which exists in the Caribean cranium, where, under a mistaken notion of beauty, the singularly depressed forehead is produced by artificial pressure in infancy. In consequence of the erect position of man, the great occipital foramen is placed nearly in the centre of the base of the skull, whereas in all animals it is placed behind the centre, and in most at the back part of the head. The want in man of the intermaxillary bone which is present in most animals, is considered by Camper as a characteristic of the human cranium. See Lawrance's *Physiological Lectures*; Pritchard's *Physical History of Mankind*; Blumenbach, *Decades craniorum diversarum gentium illustratæ*, Göttingen, 1800, 4to.

Crank, in *mechanics*; an iron axis with the end bent like an elbow, for the purpose of moving a piston, the saw in a sawmill, &c., causing it to rise and fall at every turn; also for turning a grindstone, &c. The common crank affords one of the simplest and most useful methods for changing circular into alternate motion, and *vice versa*. Double and triple cranks are likewise of the greatest use for transmitting circular motion to a distance. In fact, cranks belong to those few simple elements on which the most complicated machines rest, and which, like the lever, are constantly employed.

A patent has lately been taken out for an improvement of the crank, or rather it is intended as a mode of converting a reciprocating motion into a rotatory motion, as the vibratory action of the beam of a steam-engine, which is usually conveyed to the shaft through the agency of a crank, and thereby is caused to exert a rotatory power.



The parts which compose this apparatus are shown in the accompanying engraving. They consist of an eliptical frame to which racks are affixed; the central wheels are shown detached in the lower diagram. These wheels and their bosses slide loosely round the axle, and are severally locked to the axle, when the notch or clutch of the boss takes hold of the corresponding notch of the end pieces. These end pieces are confined to the axle by small projections fixed on the axle, called feathers or leaves, which fall into notches in the hollow part of the end pieces; these pieces are allowed to slide sideways, and are pressed up towards the wheels by spiral springs confined by the ends of the cylindrical case.

If it be supposed that the eliptical frame be attached by a perpendicular rod to the end of the vibrating beam of a steam-engine, and by that means be made to move up and down; the rack, as it descends, taking into the teeth of the wheel, will cause it to turn round, and the notch of its boss locking into the clutch or end piece, will drive the axle round with it in the same direction; but as the eliptical frame, ascends, the notch of the boss of the wheel will unlock itself, and the wheel will retrograde without affecting the axle. The other rack being opposite to the other wheel, which drives round its boss, now locking with the other end piece, causes the axle to continue revolving in the same direction as before.

Thus it will be perceived that the racks of the reciprocating frame, acting in the teeth of the wheels, will cause them to perform a reciprocating motion on their axis, and by their occasional locking to the clutch pieces, will communicate to the axle a continuous rotatory motion.

Crape; a light transparent stuff, like gauze, made

of raw silk or worsted, gummed and twisted on the mill, woven without crossing, and much used in mourning.—They are either craped or smooth. The silk destined for the first is more twisted than that for the second, it being the greater or less degree of twisting, especially of the warp, which produces he crisping given to it. Crapes are all dyed raw. This stuff came originally from Bologna; but, till of late years, Lyons is said to have had the chief manufacture of it. It is now manufactured in various parts of Great Britain. The crape brought from China is of a more substantial fabric.

Crayons; a general name for all coloured stones, earths, or other minerals and substances used in designing or painting in pastel, whether they have been beaten and reduced to a paste, or are used in their primitive consistence, after being sawn or cut into long narrow slips. The sticks of dry colours which go under this name, and which are cemented into a friable mass, by means of gum or size, and sometimes of clay, afford a very simple means of applying colours, being merely rubbed upon paper, after which the shades are blended or softened by means of a stump or small roll of leather or paper. The drawings require to be protected by a glass covering, to save them from being injured, unless some means have been adopted to fix them, so that they may not be liable to be rubbed off. This may be done by brushing the back of the paper with a strong solution of isinglass, or by passing the drawing through a powerful press, in contact with a moist paper.

Cream of Tartar. See Tartar.

Crescendo, or Cres. By the term *crescendo*, the Italians signify that the notes of the passage over which it is placed are to be gradually swelled. This operation is not of modern invention. The ancient Romans, as we learn from a passage in Cicero, were aware of its beauty, and practised it continually.

Crescendo is also the name of a musical instrument, invented in 1778, by the counsellor Bauer, in Berlin, which is played like a piano, and is furnished with wire strings.

Crest is used to signify the rising on the defensive armour of the head, also the ornament frequently affixed to the helmet, such as a plume or tuft of feathers, a bunch of horse-hair, &c. Warriors have always been in the habit of adorning their persons; and the helmet, from its conspicuousness, is very naturally chosen as the place of one of the principal ornaments. We learn from Homer (*Il.* iii. 336), that the crests of the earlier Greeks were of horse-hair; afterwards plumes, especially red ones, were adopted. (Virg. *Æn.* ix. 50, 271, 808.) To gain an enemy's crest was accounted an honourable atchievement, as it was reckoned among the *spolia*. The crests of commanders were generally larger than those of common soldiers.

In the middle ages, when rank and honours became hereditary, and particular heraldic devices were appropriated to particular families, the crest became a distinguishing hereditary mark of honour. It denotes, in heraldry, a figure placed upon a wreath, coronet; or cap of maintenance, above both helmet and shield; as, for instance, the crest of a bishop is the mitre. The crest is considered a greater criterion of nobility than the armour generally. It is commonly a piece of the arms, as that of Castile is a castle. Crests, therefore, form an important subject in the science of heraldry.

We take two very beautiful examples of the crest. The head on the right hand is ornamented with one of the richest and most beautiful of the Greek crests, The second belongs to the chivalry of modern times. It may be proper to add, that the Æginetan statues had crests ornamented with horse-hair, similar to those worn by many of our cavalry regiments in the present day.

Cretinism, in *medicine*, close approaches to rickets in its general symptoms. It differs principally in its tendency to that peculiar enlargement of the thyroid gland, which, in France, is denominated *goître*, and in the mental imbecility which accompanies it from the first. The enlargement of the gland does not always, however, accompany the other symptoms, though it does generally. Cretinism was first distinctly noticed and described by Plater, about the middle of the 17th century, as occurring among the peasants in Carinthia and the Valais. It was afterwards found, in a still severer degree, in other valleys of Switzerland, and the Alps generally. It has since been detected in various other regions, where the country exhibits similar features, as among a miserable race called *Cagots*, inhabiting the hollows of the Pyrenees, whose district and history have been described by Mr. Raymond; and in Chinese Tartary, where it is represented as existing by Sir George Staunton. On the first discovery of cretinism, it was ascribed by some to the use of snow-water, and by others to the use of water impregnated with calcareous earth, both which opinions are without foundation. The first is in a measure disproved by the fact that persons born in places contiguous to the glaciers, and who drink no other water than what flows from the melting of ice and snow, are not generally subject to this disorder; and, that the disorder is observed in places where snow is unknown. The second is contradicted by the fact, that the common water of Switzerland, instead of being impregnated with calcareous matter, excels that of most other countries in Europe in purity and flavour. The water usually drank at La Batia and Martigna is from the river Dranse, which flows from the glacier of St. Bernard, and falls into the Rhone. It is remarkably free from earthy matter, and well tasted. At Berne, the water is extremely pure; yet, as Haller remarks, swellings of the throat are not uncommon in both sexes, though cretinism is rare. As comfortable and

congenial warmth forms one of the best auxiliaries in attempting the cure of both cretinism and rickets, there can be no doubt that the chill of snow-water must considerably add to the general debility of the system when labouring under either of these diseases, though there seems no reason for supposing that it would give rise to either. It is not difficult to explain why water impregnated with calcareous earth should have been regarded as the cause; for in cretinism, as in rickets, the calcareous earth, designed by nature for the formation of the bones, is often separated, and floats loose in various fluids of the body, for want of a sufficiency of phosphoric acid to convert it into a phosphate of lime, and give it solidity. And as it is, in consequence, pretty freely discharged in the urine, this seems to have given rise to the opinion that such calcareous earth was introduced into the system with the common water of the lakes or rivers, and thus produced the morbid symptoms. M. de Saussure has assigned the following cause of the disease. The valleys of the Alps, he tells us, are surrounded by high mountains, sheltered from currents of fresh air, and exposed to the direct, and, what is worse, the reflected rays of the sun. They are marshy, and hence the atmosphere is humid, close, and oppressive; and when to these causes we add the meager, innutritious food of the poor of these districts, their indolence and uncleanliness, with a predisposition to the disease, from a hereditary taint of many generations, we can sufficiently account for the prevalence of cretinism in such places, and for the humiliating character which it assumes. The general symptoms of cretinism are the same as those of rickets; but the disease shows itself earlier, often at birth, and not unfrequently before this period, apparently commencing with the procreation of the fœtus, and affording the most evident proofs of ancestral contamination. The child, if not deformed and diseased at birth, soon becomes so; the body is stinted in its growth, and the organs in their developement.

Crisis, *in medicine;* a point in a disease, at which a decided change for the better or the worse takes place. The crisis is most strongly marked in the case of acute diseases, and with strong patients, particularly if the course of the disease is not checked by energetic treatment. At the approach of a crisis, the disease appears to take a more violent character, and the disturbance of the system reaches the highest point. If the change is for the better, the violent symptoms cease with a copious perspiration, or some other discharge from the system. In cases where the discharge may have been too violent, and the principal organs have been greatly deranged, or where the constitution is too weak to resist the disease, the patient's condition becomes worse. In regular fevers, the crisis takes place on regular days, which are called *critical days* (the seventh, fourteenth, and twenty-first); sometimes, however, a little sooner or later, according to the climate and the constitution of the patient. A bad turn often produces a crisis somewhat sooner. When the turn is favourable, the crisis frequently occurs a little later. After a salutary crisis, the patient feels himself relieved, and the dangerous symptoms cease.

Crocket, in *architecture;* one of the small ornaments which are usually placed along the angles of pinnacles, and on the outside of pediments, tabernacles, and cupolas, in the pointed style of architecture. See Architecture.

Crocus, in *chemistry;* a term given by the older chemists to several preparations of metallic substances.

Croma, in *Italian music;* the character which in England is called a quaver.

Cromorne, in *music;* a reed stop in most of our old organs; its tone resembles a bassoon more than any other instrument.

Crop, in *agriculture,* usually signifies the corn gathered off a field in harvest.

Till the middle of the last century, the best common courses of farming in Britain consisted in a fallow, which by several ploughings, broke up and cleaned the ground, but left the soil exposed to the scorching rays of the sun, during the hottest season, without any shading crop; and on this the farmer sowed wheat, which was succeeded by peas or beans; then followed barley, or oats, or both, on one part of the farm, for the space of ten or twenty years: the other moiety, during that time, being laid out in common pasture grasses. When any change was to be made, the part in grass was ploughed and prepared, and then thrown into the same course, or rotation of crops as above: that which had been in crops was sown with mixed grass-seeds (but not clover), to lie ten or twenty years, as before. The whole arable part of the farm thus parcelled, included neither the homestead nor the standing meadow; so that an arable farm of 300 acres admitted of 150 being in grass lay, or old field, and 150 in crops. The fields which bore crops, were seldom equal in quantity; but in the following plan we have ventured to consider them so, for the better comparing the old and new systems.

No. I.

Acres.		Bushels.
37½	fallow, naked, yields nothing.	
37½	wheat	555
37½	peas or beans	555
37½	barley	740
		1850
150	in crops 4 fields	
150	in grass or hay.	
300	acres.	

The fallow, wheat, and barley crops are exhausting, that is, they deprive the land, by exhalation, of part of the vegetable nutriment deposited in it; the peas or beans, which operate as a manure, ameliorate; but the rays of the sun on the naked soil, in the hot season, cause a considerable portion of the essence of the manure, and also the ground, gradually to exhale.

The present system of rotation, or courses of crops, was introduced about the middle of the eighteenth century, and is founded on the following principles, namely; 1. To fallow, and at the same time to have a shading and ameliorating mild crop growing in the fallow, while it is under the plough or hoe; 2. Never to sow any species of corn in succession; 3. To sow clover, or an equivalent on every field of small grain; and lastly, by means of a course of well selected crops, to prevent the soil from resting, hardening, and running into weeds.

By this method, entire farms are continued in a constant rotation under four, six, or eight divisions, or fields, in such a manner as to improve the soil, and consequently to produce a larger income.

Acres.	No. II.	Bushels.
60	Barley	1200
60	Clover	—
60	Wheat	900
60	Clover	—
60	Peas or Beans	900
		3000

300 acres in 5 fields.

According to this new course, the wheat and barley exhaust the soil, while the clover and peas, or beans, ameliorate and improve it.

When we compare these two systems of rotation of crops, the latter is evidently the most profitable, as the 120 acres in clover are far superior to the 150 acres of common grasses on the "hide-bound" soil of the lay, or old field; and the grain and straw are more advantageous, in the proportion of 300 to 185. Clover, peas, and beans (if sown in drills, and kept clean from weeds by hoeing), are inoffensive, and even ameliorating.—They all shade the ground during the hottest season of the year. Every kind of corn impoverishes the soil, and, if small, lets in weeds, which, together with rest, bind and foul the land.

The superiority of the new course of crops is still farther evinced by a series of conclusive experiments made by the late A. Young. He divided three acres of old upland pasture into thirty-six squares of nine roods each, which he planted with beans, peas, wheat, barley, oats, cabbages, clover, potatoes, &c., in different rotations, with various success. From these comparative trials he drew the following practical inferences, which we recommend to the serious attention of our agricultural readers.

1. That potatoes exhaust the land more than any other fallow crop hitherto tried; and in some courses to a greater degree than barley or even wheat.

2. That potatoes will not yield a tolerable crop, even on old lay newly broken up, without the aid of dung, and not a profitable one even with it.

3. That barley, beans, and oats, succeed much better than wheat, after potatoes.

4. That beans are the most valuable fallow crop on new land of this quality.

5. That the promotion of the fertility of old turf, depends much on the number of bean crops introduced; as the more frequently they are planted, the better the succeeding crops of wheat corn will be: and three successive years of beans are attended with an extraordinary produce of wheat.

6. That beans and barley, and beans and wheat, alternately, are both courses of great produce and advantages.

7. That the introduction of beans in proper rotations, tends to remedy the evil of such courses.

8. That successive crops of white corn destroy that fertility which different rotations will preserve in new ground: and that three such crops will render the land extremely foul and unprofitable.

9. That the two most productive courses are, beans and barley alternately; the former being the most abundant, but the latter the most profitable from the saving of tillage.

10. That four crops of beans, and one of wheat, even with the drawback of one years' cabbages, is the third course in profit; and the land will be left in such order, as to make it, perhaps, the first.

11. That the most unproductive, and in a still greater degree, the more unprofitable courses, are those in which turnips, cabbages, and potatoes most frequently occur.

12. That on such new land, oats are the best white grain that can be sown, as they yield very extraordinary and valuable crops.

The same intelligent cultivator, consequently, recommends the following course, which is calculated to prove the most profitable:—

1. Beans.
2. Oats.
3. Beans.
4. Oats.
5. Beans.
6. Oats.
7. Clover.
8. Beans.
9. Wheat.

The profit of beans in every rotation, by which the soil is not exhausted, is decisive; and oats are far more productive than either barley or wheat, while the old turf is decaying; because clover will revive the fertility which beans in the eighth year will not lessen, and wheat cannot fail, after these two successive ameliorating crops, to yield a plentiful harvest. In justice to Mr. Young, we shall observe that he proposes such a rotation only for new land, as there are circumstances that would render it inapplicable to other fields. The effects of SPADE HUSBANDRY, with reference to the amount and value of crops will be examined under that article.

CROSIER, in *astronomy*; four stars in the southern hemisphere in the form of a cross.

CROSS, in *heraldry*; is defined by Guillim, an ordinary composed of fourfold lines, whereof two are perpendicular, and the other two transverse; for so we must conceive them, though they are not drawn throughout, but meet, by couples, in four right angles near about the fesse-point of the escutcheon. The content of a cross is not always the same, for when it is not charged, it has only the fifth part of the field; but if it be charged, then it must contain the third part thereof. This bearing was bestowed on such as had performed, or, at least, undertaken some service for Christ and the Christian profession; and it is, therefore, held by several authors the most honourable charge in all heraldry. What brought it into such frequent use was the expeditions into the Holy Land, the cross being the ensign of that war. Several of the religious orders also employed the cross as the sole ornament of their banners; and on its passage through the public streets it was considered as incumbent on those who beheld it to make due reverence, as when the "host" was conveyed along.

CROSS, in *architecture*. This peculiar figure has been adopted very generally by the architects in the construction of religious edifices. Architectural antiquaries have two sorts of crosses, the Greek and Latin. The Greek cross has its arms at right angles, and all of equal length, whereas the Latin cross has one of its limbs much longer than the other three. St. Peter's at Rome was originally intended to be of the latter form, but the plan was afterwards changed to that of a Greek cross. The Cathedral of St. Paul's is a Latin cross, with its base spread with a species of second transept, which renders the breadth of the western front much more symmetrical.

This was also a very common species of architectural ornament for decorating cemetries, market places, or commemorating any peculiar event. One example of this species of cross, combining sculp-

ture with masonry, will give a general notion of their character.

Cross, in *surveying*; an instrument consisting of a brass circle, divided into four equal parts, by two lines intersecting each other at the centre; at the extremity of each line there is a sight fixed, standing perpendicularly over the line, with holes below each slit, for the better discovery of distant objects.

Cross-bar Shot are missiles with iron bars crossing through them, sometimes standing out six or eight inches at both sides. They are used at sea for injuring the enemy's rigging, and in sieges, for destroying the palisades in the covert-way, ditches, &c.

Cross-Bow; formerly a very common weapon for shooting, but not long used in war after the invention of fire-arms. It is a strong wooden or steel bow, fixed to a stock, stretched by the spanner, and shot off by the trigger fixed to the stock. All kinds of weapons, in which the bow was fastened to the stock, were called *cross-bows*, some of which were attached to carriages, and drawn by horses. There was a small kind, from which were shot little balls. To the larger sort were attached instruments for bending the bow. There are some societies still existing in Germany, who exercise with the cross-bow.

Cross Staff; an instrument commonly called the fore-staff, used by seamen to take the meridian altitude of the sun or stars.

Crosselet; a little or diminutive cross, used in heraldry, where the shield is frequently seen covered with crosselets, also fesses and other honourable ordinaries, charged or accompanied with crosselets. Crosses frequently terminate in crosselets.

Cross Fire, in the art of war, is when the lines of fire, from two or more parts of a work, cross one another. It is frequently made use of to prevent an enemy's passing through a defile. The flanks, as well as the faces of two adjoining bastions, afford the means of cross fire, as do also the faces of two adjoining redoubts.

Crotchet, in *music*; one of the notes or characters of time. In length it is equal to half the minim, or double the quaver.

Crotchet, in *printing*; a sort of straight or curved line, always turned up at each extreme; serving to link such articles as are to be read together; and used in analytical tables, &c., for facilitating the divisions and sub-divisions of any subject.

Crotchets are also marks or characters, serving to inclose a word or sentence, which is distinguished from the rest, being generally in this form [ ].

Croton Oil is expressed from the seeds of an East Indian plant, and is one of the most valuable of the late additions to the materia medica. It is so strongly purgative, that one drop is a full dose, and half a drop will sometimes produce a powerful effect. It is also found to produce the same effect when rubbed upon the tongue, or even upon the skin. It is so active, that it should never be used but under the direction of an experienced physician. In the hands of such, it is of great value, as its small bulk and insipid taste render it serviceable in cases in which no common medicine can be used, and its great power makes it operate when other medicines fail. It has been given to the extent of eight or ten drops, in a bad case of *ileus*, which it cured, without producing any bad symptoms. It should, however, be used with great caution.

Croup; a disease that mostly attacks infants, who are suddenly seized with a difficulty of breathing and a crouping noise; it is an inflammation of the mucous membrane of the windpipe, inducing the secretion of a very tenacious, coagulable lymph, which lines the air passages and impedes respiration. The croup does not appear to be contagious. It seems, however, peculiar to some families; and a child, having once been attacked, is very liable to a return. It is confined to young children, and has rarely been known to attack a person arrived at the age of puberty. The application of cold seems to be the general cause which produces this disorder, and therefore it occurs more frequently in the winter and spring than in the other seasons.

It has been said, that it is most prevalent near the sea-coast; but it is frequently met with in inland situations, and particularly those which are marshy. Some days previous to an attack of the disease, the child appears drowsy, inactive, and fretful; the eyes are somewhat suffused and heavy; and there is a cough, which, from the first, has a peculiarly shrill sound; this, in the course of two days, becomes more violent and troublesome, and likewise more shrill. Every fit of coughing agitates the patient very much; the face is flushed and swelled, the eyes are protuberant, a general tremor takes place, and there is a kind of convulsive endeavour to renew respiration at the close of each fit. As the disease advances, a constant difficulty of breathing prevails, and the head is thrown back in the agony of attempting to escape suffocation. There is not only an unusual sound produced by the cough (something between the yelping and barking of dog), but respiration is performed with a hissing noise, as if the windpipe was closed up by some slight, spongy substance. The cough is generally dry; but if any thing is spit up, it has either a purulent appearance, or seems to consist of films resembling portions of a membrane.

Where great nausea and frequent retching prevail, coagulated matter of the same nature is brought up. With these symptoms, there is much thirst, and an uneasy sense of heat over the whole body, a continual inclination to change from place to place, great restlessness, and frequency of the pulse. In an ad-

vanced state of the disease, respiration becomes more stridulous, and is performed with still greater difficulty, being repeated at longer periods, and with greater exertions, until, at last, it ceases entirely.

The croup frequently proves fatal by suffocation, induced either by spasm affecting the glottis, or by a quantity of matter blocking up the air passages; but when it terminates in health, it is by a resolution of the inflammation, by a ceasing of the spasms, and by a free expectoration of the matter exuding from the trachea, or of the crusts formed there. The disease has, in a few instances, terminated fatally within twenty-four hours after its attack; but it more usually happens, that where it proves fatal, it runs on to the fourth or fifth day. Where considerable portions of the membranous films, formed on the surface of the trachea, are thrown up, life is sometimes protracted for a day or two longer than would otherwise have happened.

Dissections of children, who have died of the croup, have mostly shown a preternatural membrane lining the whole internal surface of the upper part of the trachea, which may always be easily separated from the proper membrane. There is likewise usually found a good deal of mucus, with a mixture of pus, in the windpipe and its ramifications. The treatment of this disease must be conducted on a strictly antiphlogistic plan. It will commonly be proper, where the patient is not very young, to begin by taking blood from the arm or the jugular vein; several leeches should be applied along the fore part of the neck. It will then be right to give a nauseating emetic, ipecacuanha with tartarized antimony, or with squill, in divided doses; this may be followed up by cathartics, diaphoretics, digitalis, &c. Large blisters ought to be applied near the affected part, and a discharge kept up by savin cerate, or other stimulant dressing. Mercury, carried speedily to salivation, has in several instances arrested the progress of the disease, when it appeared proceeding to a fatal termination.

As the inflammation is declining, it is very important that free expectoration should take place. This may be promoted by nauseating medicines, by inhaling steam, and by stimulating gargles.

Where there is much wheezing, an occasional emetic may relieve the patient considerably, and, under symptoms of threatening suffocation, the operation of bronchotomy has sometimes saved life. Should fits of spasmodic diffiulty of breathing occur in the latter periods of the disease, opium joined with diaphoretics, would be most likely to do good. Napoleon, on the occasion of the death of his nephew, the Prince of Holland, of this disease, offered a premium of 12,000 francs for the best treatise on the croup. Of eighty-three essays, which were presented to the committee of twelve members assembled for the examination at Paris, in 1811, two were acknowledged as the best, one by Iurine, in Geneva, and the other by Albers, of Bremen, between whom the prize was divided.

Crow, in *mechanics;* a kind of iron lever with a claw at one end, and a sharp point at the other; used for heaving or purchasing great weights.

Crow's Feet, in the *military art;* machines of iron, having four points, each about three or four inches long, so made, that whatever way they fall there is still a point up: they are thrown upon breaches, or in passes were the enemy's cavalry are to march.

Crown. In the early ages, when men were fond of expressing all their feelings by outward signs, a wreath of flowers or leaves was naturally one of the first emblems of honour or of joy. Such was the ornament of the priest in the performance of sacrifice, of the hero on his return from victory, of the bride at her nuptials, and of the guests at a feast. The ancient mythology, which gave every thing a distinct beginning and a poetical origin, ascribes the invention of wreaths to Prometheus, who imitated, with flowers, the fetters which he had borne for his love to mankind, whom he had created. According to Pliny, wreaths were first made of ivy, and Bacchus first wore them. In process of time, they were made of very different materials. Those worn by the Greeks at feasts in honour of a divinity, were made of the flowers of the plant consecrated to the god. Wreaths of roses afterwards became very common. In some cases, wreaths were even made of wool. Wreaths of ivy and amethyst were worn, by the Greeks, on the head, neck, and breast, at entertainments, with a view to prevent drunkenness. Mnesitheus and Callimachus, two Greek physicians, wrote entire books on wreaths, and their medical virtues. Corpses were covered with wreaths and green branches. Lovers adorned with wreaths and flowers the doors of their mistresses, and even captives, who were to be sold as slaves, wore wreaths; hence the phrase *sub corona venire* or *vendere.* The beasts sacrificed to the gods were also crowned. Wreaths, in process of time, were made of metal, in imitation of flowers, or of the fillet which the priest wore round his head when he sacrificed, which was called *διάδημα.* This attribute of distinction was early adopted by the kings, when they united in their persons the temporal and spiritual power. Among the various crowns and wreaths in use among the Greeks and Romans were the following:

Corona agonothetarum; the reward of the victor in the great gymnastic games.

Corona aurea (the golden crown); the reward of remarkable bravery.

Corona castrensis; given to him who first entered the camp of the enemy.

Corona civica; one of the highest military rewards. It was given to him who had saved the life of a citizen.

Corona convivalis; the wreath worn at feasts.

Corona muralis; given by the general to the soldier who first scaled the enemy's wall.

Corona natalitia; a wreath which parents hung up before the door at the birth of a child. It was made of olive branches if the child was a boy, and of wool if a girl.

Corona navalis; the next in rank after the civic crown, was given to him who first boarded and took an enemy's vessel.

Corona nuptialis; a crown or wreath worn by brides. The bridegroom, also, and his relations, on the day of the wedding, adorned themselves with wreaths. At first, the *corona nuptialis* was of flowers; afterwards of gold or silver and precious stones.

Corona obsidionalis; a reward given to him who delivered a besieged town, or a blockaded army. It was one of the highest military honours, and very seldom obtained. It was made of grass; if possible of such as grew on the delivered place.

Corona triumphalis; a wreath of laurel which was given, by the army, to the *imperator.* He wore it on his head at the celebration of his triumph. Another

crown of gold, the material of which (*coronarium aurum*) was furnished by the conquered cities, was carried over the head of the general. The wreaths, conferred at the great games of Greece, were of different kinds; at the Olympic games, of wild olive; at the Pythian games, of laurel; at the Nemean games, first of olive, then of parsley; at the Isthmian games, a wreath of pine leaves, afterwards of parsley; subsequently pine leaves were resumed.

In the middle ages, crowns became exclusively appropriated to the royal and imperial dignity; the coronets of nobles were only borne in their coats of arms. From the Jewish king being called, in the Scriptures, *the anointed of the Lord*, a kind of religious mystery and awe became attached to crowned heads, which, in most countries, continues to the present day, though history has shown us abundantly that crowns often cover the heads of very weak or very wicked individuals, and that there is no great mystery about their origin; some having been obtained by purchase, some by crime, some by grants from a more powerful prince, some by contract, some by choice, but, on the whole, comparatively few in an honest way. The iron crown of Lombardy, preserved at Monza, in the territory of Milan, is a golden crown set with precious stones, with which in former times the Lombard kings were crowned, and at a later period, the Roman-German emperors, when they wished to manifest their claims as kings of Lombardy. An iron circle, made, according to the legend, out of a nail of Christ's cross, which is fixed inside, gave rise to the name. Agilulf, king of Lombardy, was the first person crowned with it (in 590). Charlemagne was crowned with it in 774. Napoleon put it on his head in 1805, and established the order of the iron crown. In 1815, when Austria established the Lombardo-Venetian kingdom, the emperor admitted the order of the iron crown among those of the Austrian empire.—*Crown* is used, figuratively, for the royal power, in contradistinction either to the person of the monarch, or to the body of the nation, with its representatives, interests, &c. Thus, in modern times, the word *crown* is used, on the European continent, to express the rights and prerogatives of the monarch considered as a part of the state, which includes all powers—the legislative, judicial, &c. Thus the crown domains are distinguished from the state or national domains. In France, a difference is even made between the crown domains and the private domains of the king; the former are inalienable, and belong to the reigning monarch, whilst the second may be treated like any other private property. The distinction between crown and state, of course, does not exist in perfectly arbitrary governments.—*Crown-officers* are certain officers at the courts of European sovereigns. Formerly, when the different branches of government were not accurately defined, they were often, or generally, also state officers, as in the old German empire, and still in Hungary. The offices were generally hereditary; but, of late years, they are almost exclusively attached to the court; the title, in a few cases, being connected with military dignities, as for instance, in France, where civil and military grand officers of the crown have always existed.

Crown, in an ecclesiatical sense, is used for the tonsure, the shaven spot on the head of the Roman Catholic priests, where they received the ointment of consecration. See TONSURE.

CROWN, in *architecture*, denotes the uppermost member of the cornice.

CROWN, in *commerce*; a coin, used in every part of the world, of about the same relative value. It rarely exceeds five shillings and sixpence.

CROWN, in *heraldry*, is used for the representation of that ornament, in the mantling of an armory, to express the dignity of the person who bears it. The crown here is of more antiquity even than the helmet; and it was used as a symbol of victory and triumph.

CROWN GLASS, the best kind of window-glass, the hardest and most colourless, is made almost entirely of sand and alkali and a little lime, without lead or any metallic oxide, except a very small quantity of manganese, and sometimes of cobalt. Crown glass is used, in connection with flint glass, for dioptric instruments, in order to destroy the disagreeable effect of the aberration of colours. Both kinds of glass are now made, in the highest perfection, in Benedictbeurn, where Reichenbach's famous manufactory of optical instruments is situated.

CROWTH, or CRUTH; a musical instrument, formerly much in use in Wales, somewhat like the violin. It has six strings, supported by a bridge, standing in an oblique direction with respect to the strings, and is performed with a bow. Of these strings, which are six in number, the first four are conducted from the tail-piece down the finger board; but the fifth and sixth, which are about an inch longer than the others, branch from them laterally, and range about the distance of an inch from the neck.

CRUCIBLE. When solid substances are to be exposed to intense heat to fuse them, or to favour their mutual chemical actions, the vessels, generally employed, at least for experimental purposes, are called crucibles. They are usually of the form of a short truncated inverted cone; some are triangular. Crucibles are made of different materials, according to the purposes for which they are to be used. A crucible ought to support the strongest heat without melting; it ought to resist the attacks of all such agents as are exposed to heat in vessels of this kind.

The Hessian crucibles are composed of sand and clay; they will support an intense heat for many hours, without softening or melting; but they are disposed to crack when suddenly heated or cooled. This inconvenience may be, on many occasions, avoided by using a double crucible, and filling up the interstice with sand, or by covering the crucible with a lute of clay and sand, by which means the heat is transmitted more gradually and equally. Those which give a clear sound when struck, and are of an uniform thickness, and have a reddish-brown colour, without black spots, are reckoned the best. They are sold in nests or sets.

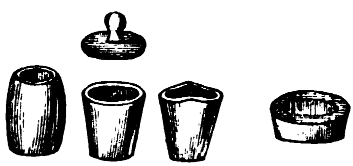
Wedgwood's crucibles, made of porcelain clay, are very excellent for all experimental purposes in the small way. They are very smooth within, and stand a strong heat. They should be coated with fire-lute before they are exposed to the action of a very intense heat.

The black lead crucibles, formed of clay and plumbago, are very durable, resist sudden changes of temperature, and may be repeatedly used; but they are destroyed when certain substances are melted in

them, and suffer a partial injury when exposed red hot to a current of air. They are also very smooth within, so that the melted matters, when poured out, do not adhere to the inside. They are totally unfit for the fusion of alkaline and saline matters, and answer best for metals and metallic substances. They may be used more than once.

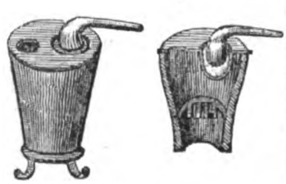
Silver crucibles (of perfectly pure silver) are particularly useful in analytical operations, for the fusion of bodies with alkalies. The utmost degree of heat they can bear is a moderate redness.

Platina crucibles, on account of the infusibility of the metal by the heat of the chemical furnaces, and its perfect unalterability by most agents, render the greatest service in the laboratory. They should always be put into a common crucible to defend them from the direct action of the coals, the slack of which affixes itself to the sides and bottom with so much obstinacy, that it cannot be detached without risk of injury to the vessel. A series of variously formed crucibles are shown beneath.



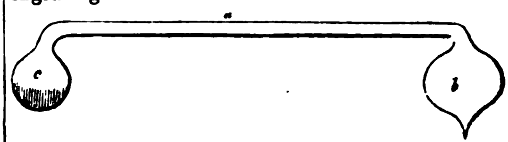
Iron crucibles resist heat extremely well; but the air, aided by the action of the fire, oxidizes them very speedily, and saline matters readily act upon them; even earths become coloured in iron crucibles, so that they cannot be employed for fusion, except in a very few cases

Crucible Furnace. This furnace is made of a common black lead crucible, from twelve to fifteen inches high, perforated at the bottom, and supported by a tripod stand. It is covered with an iron plate, into which two holes are cut; the larger hole admits the sand pot, for distillation with a retort. The fuel is put through the smaller hole. The grate rests on three notches, cut at equal distances on the inside of the body of the furnace. These furnaces serve only for moderate heats. This cheap and simple furnace admits of a variety of useful adaptations, besides those exhibited in the figure, in which we give both a section and general view. Either charcoal or coak may be employed.



Cruor, in *medicine;* the red part of the blood.

Cryophorus; a simple contrivance introduced by Dr. Wollaston, for exhibiting the degree of cold produced by evaporation. To construct the cryophorus, let a tube, having its internal diameter about one-fourth of an inch be taken, and at one extremity let an oblong cavity be formed; at the other extremity, let a ball be blown, into which, prior to closing the cavity, after producing a vacuum (in the manner practised when a thermometer is formed), let a small quantity of water be introduced. The tube between the balls, usually about twelve or fifteen inches in length, is bent, as represented in the engraving, for the purpose of keeping the water in the ball, whilst it is placed in its erect position. It will at once be understood, that all the internal space is occupied by aqueous vapour, produced at the ordinary temperature from the water, on account of the exclusion of air. In employing this apparatus, therefore, for the purpose of freezing the water in one end, it is only necessary to immerse the opposite extremity in any of the freezing mixtures—say, for example, muriate of lime and pounded ice—and the condensation of vapour will be so rapid as to produce a vacuum; which being quickly supplied with fresh vapour, will occasion an abstraction of caloric so constant and considerable from the water in the ball, as very soon to render it solid, even at the distance of two or three feet from the freezing mixture. The tube with its balls, *b* and *c*, are represented in the engraving beneath.



This experiment may be rendered still more striking, and still more illustrative of the refrigerating power of evaporation, by adopting the modification of Dr. Marcet. The empty portion, instead of being surrounded by any of the cooling mixtures above alluded to, is to be covered with flannel, which is afterwards to be moistened with water. This part of the apparatus is to be inclosed in the receiver of an air-pump, within which a shallow vessel, containing strong sulphuric acid, is placed. When the receiver is exhausted, the evaporation from the moistened surface produces so much cold as to condense the vapour within the apparatus; which being continually destroyed by this refrigeration, the water in the ball, as in the more simple experiment, is quickly frozen. The use of the acid in the small vessel will be easily understood, when it is recollected that for the more rapid evaporation it is requisite that the receiver should be constantly emptied of the vapour which it contains, and likewise, that water, either in its liquid or gaseous state, is very rapidly absorbed by concentrated sulphuric acid.

Crypt, in *architecture;* a hollow place or vault constructed under ground. The tombs of the Christian martyrs, also, were so called, where the early Christians met to perform their devotions, for fear of persecution. Hence *crypt* came to signify a church under ground, or the lower story, like that of St. Paul's, London, Lastingham Priory, and many of the ancient ecclesiastical edifices of England, Germany, and France. When crypts are on a large scale, like those of Rome, Naples, and Paris, they are then called *catacombs.*

Cryptography; the art of transmitting secret information by means of writing, which is intended to be illegible, except by the person for whom it is destined. The ancients sometimes shaved the head of a slave, and wrote upon the skin with some indelible colouring matter, and then sent him, after his hair had grown again, to the place of his destination. This is not, however, properly secret writing, but only a concealment of writing. Another sort, which corresponds better with the name, is the following, used by the ancients. They took a small stick, and wound around it bark, or papyrus, upon

which they wrote. The bark was then unrolled, and sent to the correspondent, who was furnished with a stick of the same size. He wound the bark again, round this, and thus was enabled to read what had been written.

This mode of concealment is evidently very imperfect. Cryptography properly consists in writing with signs, which are legible only to him for whom the writing is intended, or who has a key, or explanation of the signs. The most simple method is to choose for every letter of the alphabet some sign, or only another letter. But this sort of cryptography (*chiffre*) is also easy to be deciphered without a key. Hence many illusions are used. No separation is made between the words, or signs of no meaning are inserted among those of real meaning. Various keys, likewise, are used, according to rules before agreed upon. By this means, the deciphering of the writing becomes difficult for a third person, not initiated; but it is likewise extremely troublesome for the correspondents themselves; and a slight mistake often makes it illegible, even by them.

Another mode of communicating intelligence secretly, viz. to agree upon some printed book, and mark the words out, is also troublesome, and not at all safe. The method of concealing the words which are to convey the information intended in matter of a very different character, in a long letter, which the correspondent is enabled to read, by applying a paper to it, with holes corresponding to the places of the significant words, is attended with many disadvantages: the paper may be lost; the repetition of certain words may lead to discovery; and the difficulty of connecting the important with the unimportant matter, so as to give the whole the appearance of an ordinary letter, is considerable. If this is effected, however, this mode has the advantage of concealing the fact that any secrecy is intended.

Writing with sympathetic ink, or milk, lemon juice, &c., is unsafe, because the agents to make the letters visible are too generally known. Hence the *chiffré quarre*, or *chiffre indéchiffrable*, so called, has come very much into use, because it is easily applied, difficult to be deciphered, and the key may be preserved in the memory merely, and easily changed. It consists of a table, in which the letters of the alphabet, or any other signs agreed upon, are arranged under one another, thus:—

z	a	b	c	d	e	f	g	h	i	k	l	m	n	o	p	q	r	s	t	u	v	w	x	y	z
a	b	c	d	e	f	g	h	i	k	l	m	n	o	p	q	r	s	t	u	v	w	x	y	z	a

z	a	b	c	d	e	f	g	h	i	k	l	m	n	o	p	q	r	s	t	u	v	w	x	y	z

Any word is now taken for a key; *Paris*, for example. This is a short word, and, for the sake of secrecy, it would be well to choose for the key, some one or more words less striking. Suppose we wish to write in this cipher, with this key, the phrase "We lost a battle;" we must write *Paris* over the phrase, repeating it as often as is necessary, thus:—

P a r i s P a r i s P a r
We lost a battle.

We now take, as a cipher for *w*, the letter which we find in the square opposite *w* in the left marginal column, and under *p* on the top, which is *m*. Instead of *e*, we take the letter opposite *e*, and under *a*, which is *f*; for *l*, the letter opposite *l*, and under *r*, and so on.

Proceeding thus, we should obtain the following series of letters:—

mfcxlibtkmimw

The person who receives the epistle writes the key over the letters; as,

P a r i s P a r i s P a r
m f c x l i b t k m i m w

He now goes down in the perpendicular line, at the top of which is *p*, until he meets *m*, opposite to which, in the left marginal column, he finds *w*. Next, going in the line of *a* down to *f*, he finds on the left *e*.—In the same way, *r* gives *l*, *i* gives *o*, and so on. Or you may reverse the process; begin with *p*, in the left marginal column, and look along horizontally till you find *m*, over which, in the top line, you will find *w*. It is easily seen, that the same letter is not always designated by the same cypher; thus, *e* and *a* occur twice in the phrase selected, and they are designated respectively by the cyphers *f* and *w*, *b* and *k*. Thus the possibility of finding out the secret writing is almost excluded. The key may be changed from time to time, and a different key may be used with each correspondent. The utmost accuracy is necessary, because one character, accidentally omitted, changes the whole cypher. The correspondent, however, may ascertain this with considerable trouble.

Crystallography. Hauy has succeeded in developing a theory of crystals, so far as to show, that in every crystallized substance, whatever may be the difference of figure, which may arise from modifying circumstances, there is in all its crystals a primitive form, the nucleus, as it were, of the crystal; invariable in each substance, and by various modifications, which he points out, giving rise to the numerous secondary, or actually existing forms.

The fact which led to these views, is, that crystals can be mechanically divided only in certain directions, so as to afford smooth surfaces,—a fact long known by those who work on gems. Suppose a crystal of calcareous spar, a regular hexaedral prism, represented in the plates to Crystallography, *fig.* 5 and 6 [the previous elementary figures will be illustrated in another place], if we endeavour to divide it parallel to the edges which form the outlines of the basis of the prism, we shall find that three of these edges taken alternately, as the upper extremity of the edges *l f*, *d c*, *b m*, readily yield to this division by a knife struck in the proper direction; but that the other three, those which are intermediate, *f d*, *c b*, and *m l*, cannot be divided in a similar manner; and if broken by a greater force, the fracture, instead of being polished like the others, is rugged and uneven. If we repeat the experiments at the under extremity of the prism, we shall find here also that segments of three only of the edges can be detached; but these edges, instead of being the corresponding one with those divisible at the upper extremity, that is, *l f*, *d c*, *b m*, are the intermediate ones, *f d*, *c b*, and *m l*.

The six divisions compose so many trapeziums. Three of these are represented in *fig.* 6, namely, the two which cut off the edges *l f*, *c d*, represented by the dotted lines *p p*, *o o*, and *a a*, *k k*, and that which cuts off the inferior edge *d f*, and which is marked by the dotted lines *n n*, *i i*.

Each of these trapeziums will have a smoothness and lustre, from which it can be perceived that it coincides with one of the natural joinings, the assembling of which forms the prism. The prism cannot be divided in any other directions than these. But if the division be continued parallel to the first segments, it necessarily happens, that on one hand, the surfaces of the bases of the prism become narrower; and that, on the other hand, the heights of the sides diminish; and at the point at which continuing the section, the bases disappear, the prism will be changed into a dodecaedron, with pentagonal faces (*fig.* 7); six of which, *o o i*, O *e*, *o* I *k i i*, &c., are the remains of the sides of the prism, and the other six, E A I *o o*, O A K *i i*, &c., are the immediate results of the mechanical division.

In this, and the two succeeding figures, the hexaedral prism, which circumscribes the solid extracted from it in the division, is still represented to show better the progress of the operation.

Beyond this point, the planes at the extremity preserve their figure and dimensions, while the lateral planes continue to diminish in height, until the points *o*, *k*, of the pentagon *o*, I, *k*, *i i*, coinciding with the points *i*, *i*, and also have the other points similarly situated, having a like coincidence, each pentagon is reduced to a single triangle, as represented in *fig.* 8.

Lastly, by continuing the sections, the triangles are made to disappear; so that there remains no vestige of the surface of the original prism; but in place of it we have the obtuse rhomboid E A I O (*fig.* 9), which is therefore the nucleus or primitive form.

This discovery of the method of dividing a crystal was made by Hauy, in examining a crystal of calcareous spar, which had been detached from a group of which it formed a part. He observed that the fracture had happened at one of the edges of the base of the prism, and that its surface was perfectly smooth and regular. Attempting to detach a segment in a similar direction from the contiguous edge, he could not succeed, but the one next to it was easily divided; and proceeding in this manner, he was able to effect the mechanical division of the crystal in the manner already explained. Struck with the important result of the experiment, he applied the same method to other crystalline forms of the same substance, and obtained from them the same result; the crystal, whatever was its figure, being by this mechanical division converted into a rhomb. Thus, in the dodecaedron, composed of two six-sided pyramids joined by the base, the primitive form may be obtained at once by making a first section, on the edges E O, O I, *fig.* 10; a second, on the edges I K, G K; a third, on G H, E H; a fourth, on O I, I K; a fifth, on G K, G H; and, lastly, a sixth, on E H, E O; and the result is, that these edges become the same with the lateral edges of the primitive form, as may be perceived from mere inspection of *fig.* 11, which represents this primitive form described in the dodecaedron. He then applied it to other crystalline substances, and found, that from these also, by discovering the joints by which the laminæ composing the crystals were united, a certain primitive form might be extracted. That of fluor-spar is an octaedron; and that of the heavy-spar, a prism with rhomboidal bases; of corundum, a rhomboid somewhat acute; of beryl, a hexaedral prism; and of the Elba iron-ore, a cube. Each of these forms is constant with regard to the species, and is that from which all the forms of the varieties, often extremely numerous, are derived. The latter are denominated by Hauy secondary forms. Sometimes, though rarely, the primitive and secondary forms are the same. It is not every crystallized substance, however, that admits of this mechanical analysis. But, with regard to those that have hitherto refused it, Hauy has remarked, that their surface straited in a certain

London. Published by William Orr, Paternoster Row, May 29th 1833.

direction, or the relation subsisting among the different secondary forms of the same substance, afford indications which lead to the determination, with at least much probability, of their primitive forms.

Such is the process, by which Hauy establishes what he names the "primitive form of crystals," and which he defines, "a solid of a constant form, inserted symmetrically in all the crystals of the same species, and the faces of which observe the directions of the layers, which compose these crystals." The primitive forms hitherto observed, are reduceable to six: the parallelopipedon, which includes the cube, the rhomb, and all the solids which are terminated by six faces parallel two and two; the tetraedron; the octaedron; the regular hexaedral prism; the dodecaedron, with equal and similar rhomboidal planes; and the dodecaedron with triangular planes.

Hauy carries the division of crystals still farther, however, than the primitive forms. The solid which constitutes it, is not the last term of the mechanical analysis; it may always be still farther subdivided parallel to its different faces, and sometimes even in other directions. All the enveloping matter is equally divisible by sections parallel to the faces of the primitive forms; and the only limit to this possible division is that placed by the composition of the substance. The calcareous spar, to take it as an example, may be reduced to a particle beyond which the division cannot be carried without resolving it into its elements, lime and carbonic acid, or at least it may be resolved to a particle beyond which, if its minuteness allowed us to operate upon it, it is demonstrable its figure would not change. To these last particles, the result of the mechanical analysis, Hauy gives the name of integrant particles, and their union constitutes the crystal. Their forms, so far as experiment has been carried, are three: the tetraedron, the simplest of the pyramids; the triangular prism, the simplest of prisms; and the parallelopipedon, the simplest of solids, which have their faces parallel, two and two. There is little doubt that it is between these that the attraction of cohesion is immediately exerted.

The primitive forms, and the figures of the integrant particles, being determined, it remains, to complete the theory of the structure of crystals, to show by what arrangements the secondary forms, in other words, the actually existing crystals, are produced.

The neucleus of the crystal is the symmetrical solid which constitutes its primitive form, arising from the union of the integrant particles, either by their faces or their edges; and the additional matter, which forms the crystal, consists of layers of these particles superadded to that neucleus, and arranged on its faces; and to account for the formation of the crystal under a figure different from that of its primitive form, these layers, as they recede from it, are supposed to decrease, in the space they occupy, from the regular abstraction of one or more ranges of the integrant particles. This decrease may take place in various modes; and according to these, different figures of crystallization will be produced. Thus, to take the simplest example, let us suppose the primitive form is a cube; it is easy to conceive, that on each of its six sides may be reared a series of decreasing layers, or laminæ, composed entirely of cubical particles, each layer diminishing on each of its edges, by one row of the minute cubes of which it consists. The laminæ thus decreasing as they recede from the base on which they rest, until the apex consists of a single particle, it is obvious, that on each side of the cube, a four-sided pyramid will be formed. Two of these are represented, (*fig.* 12.) A B C D, G B C G.

We shall thus have, then, six four-sided pyramids, and of course twenty-four triangles, such as A B C, B C E, C E G, &c. But since the decrease is uniform on all the sides, as from the line B C, to A, and from the same line to E, it must also be uniform from A, to E; it is obvious, therefore, that the side A, B, C, of the one pyramid will be found exactly in the same plane as the side, B C E, of the adjacent; so that the entire surface of these will be the rhomb, A, B, E C. The case must be the same with all the others. The twenty-four triangles will therefore be reduced to twelve rhombs, and the figure will be a dodecaedron, very remote from the primitive form. Now, a crystal of this figure, and having this primitive form, would be resolved into that form, merely by cutting off the six solid angles, by sections, in the direction of the small diagonals of the sides, which go to the formation of these angles. We should thus successively uncover six squares, which will be the faces of the primitive cube.

In explaining the structure of a crystal, although the representation in the figure be such as to show the decrease of the laminæ by rows of particles of such a size as to give a surface uneven, similar to a succession of steps, it is obvious, that if we substitute for this the delicate structure of nature, the number, of laminæ may be so great, and the number of their cubical particles such, that the depression or channel at their edges will be altogether imperceptible to our senses, and the surfaces will appear perfect planes.

Such is an example of the production of a secondary from a primitive form, by a superposition of the laminæ, decreasing according to a certain law. It is obvious, that the laws of decrement may be various, and accordingly the decrements stated by Hauy are of four different kinds: 1. Decrements on the edges, or parallel to the sides, of which the above is an example. 2. Decrements on the angles, that is, decrements of which the lines are parallel to the diagonals of the faces of the primitive form. 3. Intermediate decrements, or those which are parallel to lines situated between the diagonals and edges of that form. 4. Mixed decrements, in which the number of ranges abstracted in breadth or in height give proportions, the two terms of which are beyond unity.

These four laws of decrement explain by the modifications of which they are susceptible, all the varieties of form under which crystals are presented to us. These modifications are reduced to the following: 1. Sometimes the decrements take place on all the edges, or on all the angles. 2. Sometimes, on certain edges, or certain angles only. 3. Sometimes they are uniform by one, two, three ranges, or more. 4. Sometimes the law varies from one edge to another, or from one angle to another. 5. In some cases, the decrements on the edges correspond with the decrements on angles. 6. Sometimes the same edge or the same angle undergoes successively several laws of decrements. And, lastly, there are cases in which the secondary crystal has faces parallel to those of the primitive form, and

which give rise to new modifications, from their combinations with the faces resulting from the decrements.

With such diversity of laws, the number of forms which may exist is immense, and must far exceed what have been observed. Confining the calculation to two of the simplest laws, those which produce subtractions by one or two ranges, it is shown that carbonate of lime is susceptible of 2044 different forms, a number fifty times greater than that of the forms already known; and if decrements of three and four ranges be admitted into the combination, the calculation will give 8,388,604 possible forms of the same substance. And even this number may be much augmented in consequence either of intermediate or mixed decrements being taken into account.

In concluding this sketch of crystallography, which we have extracted from the excellent *System of Chemistry*, by Murray, we have also thought it proper, with him, to give the figures of the more usual forms of crystals and their modifications, with the definitions of Werner, instead of following Hauy in his minute though valuable details.

It is necessary to premise, that the parts of which a crystal is conceived to be composed, are planes, edges, and angles. Planes, according to the usual geometrical definition, are surfaces lying evenly between their boundary lines: they are distinguished into lateral, which are considered as those parts of the surface of the body which are of the greatest extent, and which form its confines towards its smallest extent; and extreme, or terminal, which are those of smallest extent, and form the bounds of the body towards its largest extent. Edges are formed by the junction of two planes under determinate angles; they also are lateral, or those formed by the junction of two lateral planes; and terminal, formed by the junction of two terminal planes, or of a terminal with a lateral plane. Lastly, angles are formed by the junction of two, three, or more planes in one point.

Werner admits even primary figures of crystals which are susceptible of numerous modifications. These figures are,—the icosaedron, the dodecaedron, the hexaedron, which includes the cube, and the rhomb, the prism, the pyramid, the table, and the lens.

1st. The icosaedron, *fig.* 13, is a solid, consisting of twenty equi-lateral triangular planes, united under equal angles. 2d. The dodecaedron, *fig.* 14, or solid of twelve equal or pentagonal faces. 3d. The cube, *fig.* 15, or solid, composed of six quadrilateral planes united at oblique angles. 4th. The rhomb, *fig.* 16, or solid, of six quadrilateral planes, united at oblique angles. 5th. The prism, or solid, of two terminal planes, parallel, equal, and similar, connected by quadrangular lateral planes having one direction; the number of lateral planes may of course be various; the usual forms observed in crystals are, the four-sided rectangular prism, *fig.* 17; and the six-sided equiangular prism, *fig.* 19. 6th. The pyramid, or solid, the base of which is the plane of an indeterminate number of sides, and the sides triangles, the vertices of which meet in one point, forming the summit: the more common varieties of this figure, as forms of crystals, are the three-sided pyramid, or tetraedron, *fig.* 20, and the four-sided pyramid, *fig.* 21. 7th. The table, which, strictly speaking, is nothing but a very compressed prism; it is defined as composed of two parallel lateral planes, and of an indeterminate number of terminal planes, connected with the lateral planes and with each other, and small, compared with the lateral ones; the principal varieties are,—the oblique-angular, or rhomboidal four-sided table, *fig.* 22, the rectangular four-sided table, *fig.* 23, and the six-sided table *fig.* 24. Lastly, the lens, *fig.* 25, a solid, consisting only of two planes, which are curved; of which there are two varieties, one composed of two convex planes, and another composed of a convex and a concave plane. These simple figures are modified by combination, by tunication, by bevelment and by acumination.

The modifications by combination are confined to the pyramids, and these are frequent, two pyramids being joined by the base; the lateral planes of the one being set either directly on the lateral planes of the other, as in the double four-sided pyramid, *fig.* 27; *fig.* 28 is the double six-sided pyramid.

A crystal is said to be truncated, when any or all of its solid angles or edges appear cut off, so that where there would have been an edge or angle, we have a plane, as has already been represented in *fig.* 2 and 3. These two figures represent forms arising from the truncation of the cube: *fig.* 29 shows the cube with the figures and angles and edges: *fig.* 30, the six-sided prism, with truncated terminal edges: *fig.* 31, the same prism, with both the lateral and terminal edges truncated.

A crystal is said to be bevelled when its edges, angles, or terminal planes, are so altered that, instead of an angle, edge, or terminal plane, there appear two smaller converging planes, which terminate in an edge: *fig.* 32 shows the cube with bevelled edges: *fig.* 33, the three-sided pyramid, with bevelled edges: *fig.* 34, the oblique four-sided prism, bevelled on both extremities.

Lastly, the forms of crystals are altered by acumination. This is that kind of alteration in which, in place of the angles or terminal planes of a crystal, there are three or more planes converging and forming a point or edge: *fig.* 35 shows the cube, with angles acuminated by three planes set on the lateral planes: *fig.* 36, the rectangular four-sided prism, acuminated by four planes set on the lateral planes: *fig.* 37, the six-sided prism, acuminated by six planes set on the lateral planes. This kind of modification is often described as consisting of the primary form, with pyramidal terminations.

The forms of crystals, from the preceding modifications, are frequently still more altered, and rendered complicated by being superadded and combined; and by the extent of the modifications, one form frequently passes into another. The figures of crystals are likewise rendered complicated by aggregation, two or more crystals of the same substance being more or less closely united.

The theory of crystallography, introduced by Hauy, does not satisfactorily account for the formation of crystalline bodies; and Dr. Wollaston has very ingeniously proposed to consider the primitive particles as spheres, which, by mutual attraction, have assumed that arrangement which brings them as near as possible to each other. When a number of similar balls are pressed together in the same plane, they form equilateral triangles with each other; and if balls so placed were cemented together, and afterwards broken asunder, the straight lines in which they would be disposed to separate would

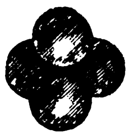
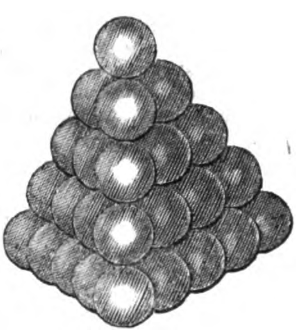
form angles of 60° with each other. A single ball placed anywhere on this stratum, as in the accompanying figure, would touch three of the lower balls, and the planes touching their surfaces would include a regular tetraedron.



A square of four balls, with a single ball resting upon the centre of each surface, would form a octoedron; and upon applying two other balls at opposite sides of this octoedron, the group will represent the acute rhomboid.



The accompanying pile represents a series of balls, with triangular faces, the bases of which are constituted of four particles. The tetraedron is confined by four of these similar and equal planes. The subject of crystallization has also especially engaged the attention of Professor Daniell, and his researches have produced some singular confirmations of Dr. Wollastone's hypothesis. If an anamorphus piece of alum be immersed in water, and left quietly to dissolve, at the end of about three weeks the observer will find that it has been unequally acted upon by the fluid; the mass will present the forms of octoedra, and sections of octoedra, as if it were, carved or stamped upon its surface.

This appearance is produced when the attraction of the water for the solid is nearly counterbalanced by its mechanical texture. The crystals formed by this species of dissection are highly curious, from their modifications and relative positions, as the same group presents the primitive form, as well as its truncations and decrements. Other salts yield other figures, and by more complicated chemical action, as of acids, upon carbonate of lime, the metals, &c., analogous results are obtained. Here, then, instead of dividing a crystal by mechanical force, its structure is gradually developed by the process of solution. In these cases two circumstances are particularly remarkable; the crystals are different, and their forms vary with the different faces of the original mass. In one direction we observe octoedra and sections of octoedra; in another, parallelograms of every dimension, modified with some determinate intersections.

If, in either of these positions, we turn the mass upon its axis, the same figure will be perceived at every quadrant of a circle; and, if we suppose the planes continued, they will mutually intersect each other, and various geometrical solids will be constructed. In this way alum alone furnishes octoedrons, tetraedrons cubes, four and eight-sided prisms, either with plain or pyramidal terminations, and rhombic parallelopipedons. It is evident, then, that no theory of crystallization can be admitted which is not founded upon such a disposition of constituent particles, as may furnish all these modifications, by mere abstraction of certain individuals from the congeries, without altering the original relative position of those which remain; and these conditions may be fulfilled by such an arrangement of spherical particles as would arise from the combination of an indefinite number of balls, endued with mutual attraction, and no other geometrical solid is adequate to the purpose; and where bodies afford crystals differing from the octoedral series, an analogous explanation is furnished, by supposing their constituent particles to consist of oblate speroids, whose axes bear different proportions to each other in different substances. Hence we may also conclude, that the internal structure of all crystals is alike, however the external shapes differ. In corroboration of the above hypothesis, we may remark, that the hexaedron is, of all geometrical figures, that which includes the greatest capacity under the least surface. If, therefore, the ultimate particles of crystalline bodies be spheres or spheroids, the greatest possible number in the least space will be included in this form. It is probable that the exterior shape of every crystal is determined by the nucleus first formed by a certain definite number of particles, which, by the power of mutual attraction, overcome the resistance of the medium in which they were suspended, or from which they were separated. This number may vary with the solvent, or other contingent circumstances. Four spherical particles, thus united, would balance each other in a tetraedral group, six in an octoedral group, and each would present particular points of attraction, to which all subsequent deposits would be directed. Now, let us imagine two nuclei formed in the same solution, whose axes run in contrary directions; their increase will consequently be in contrary directions, and each will attract a particular system of particles from the surrounding medium. If these two systems should cross each other in their course, a greater number will be brought within the sphere of mutual reaction at the point of junction, and they ought to arrange themselves in the least possible compass. The facts here answer to the theory. If we select any crystals, having others crossing them nearly at right angles, and separate them, the points of junction invariably present a hexaedral arrangement.

In connection with chemistry, the theory of crystallization opens a new avenue to the science, and frequently enables us to ascertain directly that which, independent of such aids, could only be arrived at by an indirect and circuitous route. We frequently read the chemical nature of substances in the mechanical forms. To the mineralogist an intimate acquaintance with the crystalline forms and modifications of natural bodies is essentially requisite. Indeed, the theory of crystallization may be considered as one of the great supports of that useful branch of natural history; and it is to the indefatigable exertions of Hauy that much of its present perfection is to be referred. In the arts the process of crystallization is turned to a very valuable account, in the separation and purification of a variety of substances. See Brande's *Manual of Chemistry*.

For the more minute details of this subject, particularly as relates to mineralogy, the reader is referred to the NATURAL HISTORY division of this work.

CUBE, in *geometry;* a solid body, consisting of six equal square sides. The solidity of any cube is found by multiplying the superficial area of one of the sides by the height. Cubes are to one another in the triplicate ratio of their diagonals; and a cube is supposed to be generated by the motion of a square

plane along a line equal to one of its sides, and at right angles thereto; whence it follows, that the planes of all sections, parallel to the base, are squares equal thereto, and, consequently, to one another.

Cube, or Cubic Number, in *arithmetic;* that which is produced by the multiplication of a square number by its root; thus 64 is a cube number, and arises by multiplying 16, the square of 4, by the root, 4.

Cube, or Cubic Quantity, in *algebra;* the third power in a series of geometrical proportionals continued; as, *a* is the root, *a a* the square, and *a a a* the cube.

Cube Root of any number or quantity is a number or quantity, which if multiplied into itself, and then again by the product thence arising, gives a product equal to the number or quantity whereof it is the cube root; as, 2 is the cube root of 8, because twice 2 are 4, and twice 4 are 8.

Cubic Foot of any substance; so much of it as is contained in a cube whose side is one foot.

Cubit, in the mensuration of the ancients; a long measure, equal to the length of a man's arm, from the elbow to the tip of the fingers. Doctor Arbuthnot makes the English cubit equal to 18 inches, the Roman cubit equal to 1 foot, 5.406 inches, and the cubit of scripture equal to 1 foot 9.888 inches.

Cucurbit; a glass apparatus used in experimental chemistry. It consists of an oblong vessel with a very wide mouth, on which is ground the head of a common alembic. In the accompanying engraving it is seen to enter a glass flask, which is placed to receive or condense the fluids conveyed by the pipe from the head.

Cuirass; an article of defensive armour, protecting the body both before and behind. Meyrick, in his dissertation on ancient armour, has thus distinguished the cuirasses of different nations:—1. Leathern, with a belt of the same material, worn by the Medes and Persians, before the reign of Cyrus the Great. 2. Plumated or scaled *loricæ* of steel, of which the forepart covered the breast, the front of the thighs, and foreparts of the hands and legs; the posterior part, the back, neck, and whole of the head; both parts being united by *fibulæ* on the sides: these belonged to the Parthian cavalry. 3. Scales made of horses' hoofs, sewed together with the sinews of oxen, were worn by the Sarmatians. 4. That form which was padded with wool, covered with flat rings or square pieces of brass, fastened at the sides, and cut round at the loins. 5. The Etruscans wore plain, scaled, laminated, ringed, or quilted cuishes, with straps depending from them, either of leather solely, or plated with metal; and these straps, as well as the cuirasses, were adopted by the Romans, who termed them *loricæ*.

On the Trajan column, the *loricæ* of the *hastati* and *principes* (the two first ranks) consist of several metal bands wrapped half round the body, and fastened before and behind, over a leathern or quilted tunic. Sometimes the Roman cuirass was enriched with embossed figures. The *loricæ* of the *triarii* (the third rank) were of leather only. Domitian, according to Martial, adopted the Sarmatian cuirass, which he made of the hoofs of boars. The Roman cavalry of the early period did not wear *loricæ;* but even before the *cataphractes* of Constantine (who wore flexible armour of scales and plates and rings, held together by hooks and chains, the *loricæ hamata* of Virgil—*Loricam consertam hamis auroque trilicem,* Æn. iii. 467), we read of horsemen who were *loricati.*—Among the moderns the Anglo Saxons wore leathern cuirasses (*corietæ*), which, towards the end of the ninth century, were formed of hides fitted close to the body, and jagged, or cut into the shape of leaves below. The leathern cuirass, covered with rings, was appropriated to the blood royal, or chiefs of high rank: it was borrowed from the Gauls, and called *mael,* whence our coat of *mail.* The cuirass of the thirteenth century, is shown in the accompanying figure.

The cuirass appears to have been disused in England in the time of Charles II., when bullet-proof silk was introduced. The lance having, of late years, again become an offensive weapon, the cuirass has been revived among the European cavalry. The finest part of Napoleon's cavalry were cuirassiers; and the weight of these heavily-armed soldiers gave great momentum to their charge. The cuirass leaves many vulnerable parts exposed, but, as it protects almost all the trunk, it materially diminishes the chance of wounds, and gives confidence to the soldier. It may hardly be necessary to add, that in some of the best appointed of our cavalry regiments a light cuirass has been adopted.

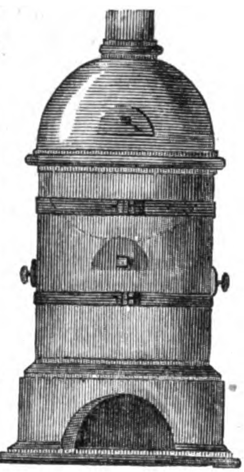
Culm; a species of coal occasionally employed in manufactories. Its *mineralogical* features will be described in the Natural History division of this work.

Culmination, in *astronomy;* the passing of a star through the meridian, because it has at that moment reached the highest point (*culmen*) of its path, with reference to the observer. Hence *culmination* is used,

metaphorically, for the condition of any person or thing arrived at the most brilliant or important point of its progress.

Cupel; a shallow earthen vessel, somewhat resembling a cup, from which it derives its name. It is formed of bone-ashes, and is extremely porous. It is used in assays, to separate the precious metals from their alloys. The process of *cupellation* consists in fusing an alloy of a precious metal, along with a quantity of lead, in a cupel. The lead is extremely susceptible of oxidation, and, at the same time, it promotes the oxidation of other metals, and vitrifies with their oxides. The foreign metals are thus removed; the vitrified matter is absorbed by the cupel, or is driven off by the blast of the bellows, as it collects on the surface; and the precious metal at length remains nearly pure. See Assay.

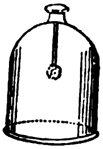
Cupelling Furnace. Under the article Assaying we gave a view of a very complete furnace for cupelling; but it may not be amiss to describe one a good deal used, and of a more portable character.



The accompaying furnace is formed of black lead, and strengthened by hoops of iron. It can be placed on the table, and may be employed for a variety of purposes. The muffle is introduced at the central opening, and the charcoal supplied at the small semi-circular opening in the dome. At the sides may be placed the nozzles of one or more pairs of bellows. This furnace cannot be used for very high temperatures, but is useful to the expermentalist.

Cupola, in *architecture;* a hemispherical roof, often used as the summit of a building. The Italian word *cupola* signifies a hemispherical roof, which covers a circular building, like the Pantheon at Rome, and the round temple at Tivoli. Many of the ancient Roman temples were circular; and the most natural form for a roof for such a building was that of a half globe, or a cup reversed. The invention, or at least the first use, of the cupola belongs to the Romans; and it has never been used with greater effect than by them. The greater part of modern cupolas (unlike those of the ancients, which are mostly hemispherical) are semi-elliptical, cut through their smallest diameter. The ancients seldom had any other opening than a large circle in the centre, called the *eye* of the cupola; while the moderns elevate lanterns on their top, and perforate them with variously formed windows, and other disfigurements. The ancients constructed their cupolas of stone; the moderns of timber, covered with lead or copper. Of cupolas, the finest, without any comparison, ancient or modern, is that of the Rotundo or Pantheon at Rome. Of modern constructions, some of the handsomest are the cupola on the Bank of England, that of St. Peter's at Rome, those of St. Paul's, London, the Hotel des Invalides, and the church of St. Genevieve at Paris, Santa Maria da Fiori at Florence, and St. Sophia at Constantinople.

Cupping; in *surgery,* the operation of applying glasses for the abstraction of blood, after dividing, by means of the scarificator, the vessels of the skin.



The apparatus in ordinary use for cupping consists of a glass bell-formed vessel, which, being inverted upon that part of the body where the punctures have been made by the lancets, an exhaustion is produced within the bell by burning a portion of the air, and the blood immediately flowing into the vacuum, by the pressure of the external air, the desired operation is effected. In removing the glass bell from the swollen part of the flesh, considerable inconvenience arises, and to remedy this is the object of Mr. Kennedy's new glass.

In the upper part of the improved glass bell, shown in the figure, an aperture is made, which is closed by a screwed cap of metal, and rendered air-tight by a collar of leather. By means of this contrivance the burner for consuming the air can be more conveniently introduced, and the glass bell be more correctly fixed than in the old apparatus.

The burning spirit is immediately introduced into the glass bell through the aperture at top; and the cap being screwed down air-tight, a portion of the air within the glass becomes consumed by the flame of the burning spirits. As soon as the glass gets cool, the blood issues from the scarification into the exhausted bell, and when a sufficient quantity has been drawn, the metal cap is unscrewed, and the air re-admitted. The bell containing the blood may now be removed without inconvenience.

Currency. See Money.

Current, a term used to express the present time: thus, the year 1833 is the current year. As applied to commerce, we say, "current coin," for the known and common coin of the country. The "price current" is the known and ordinary price at the present time.

Currents, in the ocean, are continual movements of its waters in a particular direction. In lat. 39° N., lon. 13° 40′ W., we begin to feel the effects of the current which flows from the Azores to the Straits of Gibraltar and the Canaries. Between the tropics, from Senegal to the Caribbean Sea, the general current, and that longest known, flows from east to west. Its average rapidity is from 9 to 10 nautical miles in 40 hours. It is this current which is known by the name of the *equatorial current.* It appears to be caused by the impulse which the trade-winds give to the surface of the water.

In the channel which the Atlantic has hollowed between Guiana and Guinea, under the meridian of 18° or 21° W., from 8° or 9° to 2° or 3° N. lat., where the trade-winds are often interrupted by winds which blow from the south and south-west, the equatorial current is less uniform in its direction. Near the coast of Africa, vessels are often drawn to the south-east, whilst, near the Bay of All Saints and Cape St. Augustine, upon the coast of America, the general direction of the waters is interrupted by a particular current, the effects of which extend from Cape St. Roche to Trinity Island. It flows towards the north-west, at the rate of one foot, or one foot five inches, a second. The equatorial current is felt, although slightly, even beyond the tropic, in latitude 28° N. In the basin of the Atlantic Ocean, 6 or 700 leagues from the coast of Africa, vessels, whose course is from Europe to the West Indies, find

their progress accelerated before they arrive at the torrid zone. Farther north, between the parallels of Teneriffe and Ceuta, in longitude 44° to 46° W., no uniform motion is observed

A zone of 140 leagues separates the equatorial current from that great mass of water flowing to the east, which is distinguished by its elevated temperature, and of which we shall now speak particularly. The equatorial current impels the waters of the Atlantic Ocean towards the Musquito shore and the coast of Honduras, in the Caribbean Sea. The new continent opposes this current: the waters flow to the north-west, and, passing into the Gulf of Mexico, by the strait which is formed by Cape Catoche (Yucatan) and Cape St. Antoine (Cuba), they follow the windings of the American coast to the shallows west of the southern extremity of Florida. Then the current turns again to the north, flowing into the Bahama channel. In the month of May, 1804, A. Von Humboldt observed in it a rapidity of 5 feet a second, although the north wind blew violently. Under the parallel of Cape Canaveral, the current flows to the north-east. Its rapidity is then sometimes five nautical miles an hour. This current, called the *gulf stream*, is known by the elevated temperature of its waters; by their great saltness; by their indigo-blue colour; by the train of sea-weed which covers their surface, and by the heat of the surrounding atmosphere, which is very perceptible in winter. Its rapidity diminishes towards the north, at the same time that its breadth increases. Near the Bahama bank, the breadth is 15 leagues; in lat. 28° 30′ N. it is 17 leagues; and, under the parallel of Charleston, from 40 to 50 leagues. To the east of the port of Boston, and under the meridian of Halifax, the current is almost 80 marine leagues in breadth. There it turns suddenly to the east, and passes the southern extremity of the great bank of Newfoundland.

The waters of this bank have a temperature of from 8° 7′ to 10° centigrade (7° to 8° R., 16° to 18° Fahr.), which offers a striking contrast to the waters of the torrid zone, impelled to the north by the gulf stream, and the temperature of which is from 21° to 22° 5′ (17° to 18° R., 40½° to 83° Fahr.). The waters of the bank are 6° 9′ Fahr. colder than those of the neighbouring ocean, and these are 5° 4′ Fahr. colder than those of the current. They cannot be equalized, because each has a cause of heat or cold which is peculiar to it, and of which the influence is permanent. From the bank of Newfoundland to the Azores, the gulf stream flows to the E. or E.S.E. The waters still preserve there a part of the impulse received in the Strait of Florida. Under the meridian of the islands of Corvo and Flores, the current has a breadth of 160 leagues. In lat. 33°, the equatorial current approaches very near the gulf stream. From the Azores, the current flows towards Gibraltar, the island of Madeira, and the Canaries. South of that island, the current flows to the S.E. and S.S.E., towards the coast of Africa. In lat. 25° and 26°, the current flows first S., then S.W. Cape Blanc appears to influence this direction, and in its latitude the waters mingle with the great current of the tropics.

Blagden, Benjamin Franklin, and Jonathan Williams first made known the elevated temperature of the gulf stream, and the coldness of the shallows, where the lower strata unite with the upper, upon the borders or edges of the bank. A. Von Humboldt collected much information, to enable him to trace, upon his chart of the Atlantic Ocean, the course of this current.

The gulf stream changes its place and direction according to the season. Its force and its direction are modified, in high latitudes, by the variable winds of the temperate zone, and the collection of ice at the north pole. A drop of water of the current would take two years and ten months to return to the place from which it should depart. A boat, not acted on by the wind, would go from the Canaries to the coast of Caracas in 13 months; in 10 months, would make the tour of the Gulf of Mexico; and, in 40 or 50 days, would go from Florida to the bank of Newfoundland. The gulf stream furnished to Christopher Columbus indications of the existence of land to the west. This current had carried upon the Azores the bodies of two men of an unknown race, and pieces of bamboo of an enormous size. In lat 45° or 50°, near Bonnet Flamand, an arm of the gulf stream flows from the S.W. to the N.E., towards the coast of Europe. It deposits, upon the coasts of Ireland and Norway trees and fruits belonging to the torrid zone. Remains of a vessel (the *Tilbury*), burnt at Jamaica, were found on the coast of Scotland. It is likewise this river of the Atlantic which annually throws the fruits of the West Indies upon the shore of Norway.

The causes of currents are very numerous. The waters may be put in motion by an external impulse; by a difference of heat and saltness; by the inequality of evaporation in different latitudes, and by the change in the pressure at different points of the surface of the ocean. The existence of cold strata, which have been met with at great depths in low latitutes, prove the existence of a lower current, which runs from the pole to the equator. It proves, likewise, that saline substances are distributed in the ocean, in a manner not to destroy the effect produced by different temperatures. The polar currents, in the two hemispheres, tend to the east, probably on account of the uniformity of west winds in high latitudes.

It is very probable that there may be, in some places, a double local current; the one above, near the surface of the water, the other at the bottom. Several facts seem to confirm this hypothesis, which was first proved by the celebrated Halley. In the West Indian seas, there are some places where a vessel may moor herself in the midst of a current by dropping a cable, with a sounding lead attached, to a certain known depth. At that depth, there must, unquestionably, be a current contrary to the one at the surface of the water. Similar circumstances have been observed in the Sound. There is reason to believe, that the Mediterranean discharges its waters by an inferior or concealed current. Such a mass of ocean water, flowing constantly from the torrid zone towards the northern pole, and, at any given latitude, heated many degrees above the temperature of the adjacent ocean, must exert great influence on the atmosphere.

Currying is the art of dressing cow-hides, calves'-skins, &c., principally for shoes; and this is done either upon the flesh or the grain. In dressing leather for shoes upon the flesh, the first operation is soaking the leather in water until it is thoroughly wet; then the flesh side is cleaed on a beam about seven or eight inches broad, with a knife of a peculiar construction, to a proper substance. This

is one of the most curious and laborious operations of the whole business of currying. The knife used for this purpose is of a rectangular form, with two handles, one at each end, and a double edge. After the leather is properly shaved, it is thrown into the water again, and scoured upon a board or stone commonly appropriated to that use. Scouring is performed by rubbing the grain or hair side, with a piece of pumice stone, or with some other stone of a good grit. These stones force out of the leather a white substance, called *the bloom*, produced by the oak bark in tanning. The hide or skin is then conveyed to the shade, or drying-place; where the oily substances are applied, termed *stuffing* or *dubbing*. When it is thoroughly dry, an instrument, with teeth on the under side, called a *graining-board*, is first applied to the flesh side, which is called *graining;* then to the grain side, called *bruising*. The whole of this operation is intended to soften the leather to which it is applied. Whitening or paring, succeeds, which is performed with a fine edge to the knife already described, and used in taking off the grease from the flesh. It is then boarded up or grained again, by applying the graining-board first to the grain, and then to the flesh. It is now fit for waxing, which is performed first by colouring. This is effected by rubbing, with a brush dipped in a composition of oil and lamp-black, on the flesh till it be thoroughly black: it is then sized, called *black-sizing*, with a brush or sponge, dried and tallowed; and, when dry, this sort of leather, called *waxed*, or *black on the flesh*, is curried.

The currying leather on the hair, or grain side, called *black on the grain*, is the same with currying on the flesh, until we come to the operation of scouring. Then the first black is applied to it while wet; which black is a solution of the sulphate of iron called *copperas*, in clear water, or in the water in which the skins, as they come from the tanner, have been soaked. This is first put upon the grain after it has been rubbed with a stone; then rubbed over with a brush dipped in stale urine; the skin is then stuffed, and, when dry, it is seasoned, that is, rubbed over with a brush dipped in copperas water, on the grain, till it is perfectly black. After this, the grain is raised with a fine graining-board. When it is thoroughly dry, it is whitened, bruised again, and grained in two or three different ways, and, when oiled upon the grain, with a mixture of oil and tallow, it is finished.

Curtate Distance, in *astronomy;* the distance of a planet from the sun to that point where a perpendicular, let fall from the planet, meets with the ecliptic.

Curtation, in *astronomy*, is the interval between a planet's distance from the sun, and the curtate distance.

Curtin, Curtain, or Courtin, in *fortification*, is that part of the rampart of a place which is betwixt the flanks of two bastions, bordered with a parapet five feet high, behind which the soldiers stand to fire upon the covered-way, and into the moat.

Curve, in *geometry*. The simplest objects are the most difficult to be defined, and mathematicians have never succeeded in giving a definition, satisfactory to themselves, of a line. It is equally difficult to give a satisfactory definition of a curve. Perhaps the simplest explanation of it is, *a line which is not a straight line, nor made up of straight lines*. This definition, however, is deficient in mathematical precision. Since Descartes' application of algebra to geometry, the theory of the curves has received a considerable extention. The study of the curves known to the ancients has become much easier, and new ones have been investigated. Curves form, at present, one of the most interesting and most important subjects of geometry. Such as have not all their parts in the same plane, are called *curves of a double curvature*. The simplest of all curves is the circle. The spiral of Archimedes, the conchoid of Nicomedes, the cissoid of Diocles, the quadratix of Dinostratus, &c., are celebrated curves.

Customs, in *commerce;* the duties or taxes payable upon the importation or exportation of merchandise. Custom duties seem to have existed in every country which had any foreign commerce. The Athenians laid a tax of a *fifth* on the corn and other merchandise imported from foreign countries, and also on several commodities exported from Attica. The *portoria*, or customs, charged on the commodities imported into, and exported from, the different ports in the Roman empire, formed a very ancient and important part of the public revenue. They were imposed, as Tacitus has observed, by the consuls and tribunes, when the spirit of liberty was strong among the people. The rates at which they were charged were fluctuating and various; and little is now known respecting them. In the time of Cicero, a duty of 5 per cent. was, as he himself informs us, levied on corn exported from the ports of Sicily. Under the imperial government, the amount of the *portoria* depended as much on the caprice of the prince as the exigencies of the state. Though sometimes diminished, they were never entirely remitted, and were much more frequently enlarged. Under the Byzantine emperors, they were as high as 12½ per cent.

Customs seem to have existed in England before the Conquest; but the king's claim to them was first established by stat. 3 Edw. I. (A. D. 1274), although the record is not now extant. The duties imposed by this act were on wools, woolfels (sheep-skins), and hides, and were denominated *costuma magna*, in contradistinction to the *costuma parva*, or extraordinary duties paid by aliens, and established by an ordinance of 31 Edw. I. The duties of tonnage and poundage were custom duties; the former being levied on wine by the ton, and the latter being an *ad valorem* duty on all other merchandise. In the 47th year of Edw. III. this latter duty was fixed at 6*d*.; in the 14th of Richard II. it was raised to a shilling, but three years afterwards it was reduced to the original amount. In the 2d year of Henry IV. it was increased to eightpence, and two years afterwards to a shilling. The duties of tonnage and poundage being granted to the crown, were termed subsidies; and, as the latter duty continued for a long period at the rate of one shilling in the pound, or 5 per cent., a subsidy came, in the language of finance, to signify an *ad valorem* duty of 5 per cent. The *new subsidy* imposed by the 9th and 10th of Will. III. was an addition of 5 per cent. to the duties on most imported commodities: other subsidies were levied at subsequent periods. The old or original subsidy was levied according to a book of rates, published in the reign of Charles II.; and a new book was again produced in the reign of George I.

Great confusion prevailed in the collection of the customs, in consequence of the accumulation of duties, and the complicated regulations to which they

gave rise. The embarrassment was greatly increased by special appropriation of each of the different duties on the same article, and the consequent necessity of a separate calculation for each. At the recommendation, however, of the commissioners of accounts, appointed in 1780, alterations were introduced which were productive of the very best effects. The Customs' Consolidation Act, brought in by Mr. Pitt in 1787, abolished the existing duties on all articles, and substituted in their stead one single duty on each article equivalent to the aggregate of the various duties with which it had been previously loaded. This act was founded on no less than 3000 resolutions; and it was the means of introducing a more uniform and simple system into the business of the Custom-house than had before existed. Several similar consolidations have been since effected, the last of which took place in 1825.

The collection of the custom duties is under the superintendence of the Board of Customs, which is not to consist of more than thirteen commissioners; to be reduced to eleven as vacancies occur. The treasury may appoint one commissioner, and two assistant commissioners, to act for Scotland and Ireland.

The increase of the customs' revenue will be apparent from the following view of their amount at the different periods mentioned:—

Year.	Net Revenue.
1590	£50,000
1613	148,075
1660	421,582
1688	781,987
1712	1,315,423
1792	4,407,000
1802	7,415,000
1815	11,360,000
1832	16,795,000

CUTICLE is a thin, pellucid, insensible membrane, of a white colour, that covers and defends the true skin, with which it is connected by the hairs, exhaling and inhaling vessels, and the *rete mucosum*.

CUTIS; the true skin, or a thick, fibrous, vascular, and nervous membrane, that covers the whole external surface of the body, and is the situation of the organ of touch, exhalation, and inhalation.

CUTIS ANSERINA; the rough state the skin is sometimes thrown into from the action of cold or other causes, in which it looks like the skin of the goose.

CUTLASS; a short sword used by seamen. The art of fencing with it is different from that with the small sword or broad sword. A guard over the hand is an advantage. It is, if well understood, a very effectual weapon in close contest: on account of its shortness, it can be handled easily, and yet is long enough to protect a skilful swordsman.

CUTLERY. Though cutlery, in the general sense, comprises all those articles denominated *edge tools*, it is more particularly confined to the manufacture of knives, forks, scissors, penknives, razors, and swords. Damascus was anciently famed for its razors, sabres, and swords. The latter are said to possess all the advantages of flexibility, elasticity, and hardness. These united distinctions are said to have been effected by blending alternate portions of iron and steel in such a manner, that the softness and tenacity of the former could prevent the breaking of the latter.

All those articles of cutlery which do not require a fine polish, and are of low price, are made from blistered steel. Those articles which require the edge to possess great tenacity, at the same time that superior hardness is not required, are made of sheer steel. The finer kinds of cutlery are made from steel which has been in a state of fusion, and which is termed *cast steel*, no other kinds being susceptible of so fine a polish. (See STEEL.) Table knives are mostly made of sheer steel; forks are made almost altogether by the aid of the stamp and appropriate dies; the prongs only are hardened and tempered.

Almost all razors are made of cast steel, the quality of which should be very good, the edge of a razor requiring the combined advantages of great hardness, and tenacity. After the razor blade is forged, it is hardened, by gradually heating it to a bright red heat. and plunging it into cold water. It is tempered by heating it afterwards till a brightened part appears of a straw colour. Though this is generally performed by placing them upon the open fire, it would be more equally effected by sand, or what is still better, in hot oil, or a fusible mixture, consisting of 8 parts of bismuth, 5 of lead, and 3 of tin; a thermometer being placed in the liquid at the time the razors are immersed, for the purpose of indicating the proper temperature, which is about 500° of Fahrenheit. Razors are ground crosswise, upon stones from 4 to 7 inches in diameter, a small stone being necessary to make the sides concave. They are afterwards smoothed and polished.

The handles of high-priced razors are made of ivory and tortoise-shell, but in general they are of polished horn which is preferred on account of its cheapness and durability. The horn is cut into pieces, and placed between two corresponding dies, having a recess of the shape of the handle The dies are previously heated to about 500° of Fahrenheit, and placed with the horn, in a press of such power, that, allowing a man's strength to be 200 pounds, it will be equal to 43,000 pounds. By this process, the horn receives considerable extension. If the horn is not previously black, the handles are dyed black by a bath of logwood and sulphate of iron. The clear horn handles are sometimes stained so as to imitate the tortoise-shell.

The manufacture of penknives is divided into three departments; the first is the forging of the blades, the spring, and the iron scales; the second, the grinding and polishing the blades; and the third, the handling, which consists in fitting up all the parts, and finishing the knife. The blades are made of the best cast steel, and hardened and tempered to about the same degree with that of razors. In grinding, they are made a little more concave on one side than the other: in other respects, they are treated in a similar way to razors. The handles are covered with horn, ivory, and sometimes wood; but the most durable covering is stag-horn. The most general fault in penknives is that of being too soft.

The temper ought to be not higher than a straw colour, as it seldom happens that a penknife is so hard as to snap on the edge.

The beauty and elegance of polished steel is nowhere displayed to more advantage than in the manufacture of the finer kinds of scissors. The steel employed for the more valuable scissors should be cast steel of the choicest qualities: it must possess hardness and uniformity of texture, for the sake of

acquiring a fine polish; and great tenacity when hot, for the purpose of forming the bow or ring of the scissors, which requires to be extended from a solid piece, having a hole previously punched through it. It ought also to be very tenacious when cold, to allow that delicacy of form observed in those scissors termed *ladies' scissors*. After the scissors are forged as near to the same size as the eye of the workman can ascertain, they are paired, and the two sides fitted together. The bows and some other parts are filed to their intended form; the blades are also roughly ground, and the two sides properly adjusted to each other, after being bound together with wire, and hardened up to the bows. They are afterwards heated till they become of a purple colour, which indicates their proper temper.

Almost all the remaining part of the work is performed at the grinding-mill, with the stone, the lap, the polisher, and the brush. The very large scissors are partly of iron and partly of steel, the shanks and bows being of the former. These, as well as those all of steel, which are not hardened all over, cannot be polished: an inferior sort of lustre, however, is given to them by means of a burnisher of hardened polished steel, which is very easily distinguished from the real polish by the irregularity of the surface. By a combination of platinum and some other metals in fine cutlery, it has lately been much improved.

Cutter; a small vessel, furnished with one mast, and rigged as a sloop. Many of these fast-sailing vessels are used by smugglers, and are also employed for the purpose of apprehending them. In the latter case they are called *revenue cutters*.

Cut-Water; the sharp part of the head of a ship below the beak, so called because it cuts or divides the water before it comes to the bow, that it may not come too suddenly to the breadth of the ship, which would retard it.

Cyanogen. This gaseous compound was discovered, in 1815, by Gay Lussac. It may be obtained from dry and pure *cyanuret of mercury*. This substance when heated in a small glass tube to dull redness, becomes black, and a quantity of mercury passes over and condenses in the cold part of the tube: the gas which is at the same time evolved, must be collected over mercury.

It has a penetrating and very peculiar smell, somewhat resembling that of bitter almonds; it burns with a beautiful purple flame. Its specific gravity to hydrogen is 24.4; 100 cubic inches weighing 54.9 grains. Water dissolves 4.5 volumes, and alcohol 23 volumes of this gas. The aqueous solution reddens vegetable blues; and according to Vauquelin is subject to spontaneous decomposition, being gradually converted into carbonic and hydrocyanic acids, ammonia, a peculiar acid, which he calls the *cyanic*, and a brown substance containing carbon; the ammonia saturates the acids, and the carbonaceous compound is deposited. These changes are referable to the mutual re-action of the elements of cyanogen upon those of water. (See Hydrocyanic or Prussic Acid.)

Cycle is used for every uniformly returning succession of the same events. On such successions or cycles of years rests all chronology, particularly the calendar. Our common solar year, determined by the periodical return of the sun to the same point in the ecliptic every body knows, contains 52 weeks and 1 day and leap-year a day more. Consequently, in different years, the same day of the year cannot fall upon the same day of the week; but, as, for example, the year 1814 began with Saturday, 1815 with Sunday, 1816 with Monday; but 1817, because preceded by a leap-year, began not with Tuesday, but with Wednesday.

If we count only common years, it is manifest that, from seven years to seven years, every year would begin again with the same day of the week as the seventh year before; or, to express the same in other words, after seven years, the dominical letter would return in the selfsame order. But as every fourth year, instead of a common year, is a leap-year, this can only take place after 4×7, or 28 years. Such a period of 28 years is called a *solar cycle*, and serves to show the day of the week falling on the first day of January in every year. For this purpose it is only requisite to know with what day of the week a particular year began, and then to prepare a table for the first days of the 27 following years. It is the custom now to fix the beginning of the solar cycle at the ninth year B. C., which was a leap-year, and began with Monday.

If you wish to know what day of the week the new-year's day of any year of our reckoning is, you have only to add nine to the number of the year, and then, after dividing this sum by 28, the quotient gives, of course, the number of complete cycles, and the remainder shows what year of the solar period the given year is, of which the table above mentioned gives the day of the week with which it begins. But this reckoning is only adapted to the Julian calendar. In the Gregorian, it is interrupted by the circumstance that, in 400 years, the last year of the century is three times a common year. Hence this reckoning will not give the day of the week for the first day of the year; but from 1582 (the commencement of the Gregorian calendar) to 1700, for the 11th, from 1700 to 1800 for the 12th, in the 19th century for the 13th day of the year, and so on, from which we must then reckon back to the new-year's day. Hence it is far more convenient to prepare a table for the beginning of a century (for example, for 1801, which began with Thursday), and divide by 28 the number of years from that to the given year, and, with the remainder, seek in the table the day of the week for the first day of the year.

Besides this, another cycle is necessary for the determination of festival days, by the aid of which the feast of Easter, by which all the moveable feasts are regulated, is to be reckoned. Easter depends on the first full moon after the vernal equinox.

The lunar cycle is a period of 19 years, after which the new moon falls again on the same day of the month. As the time from one new moon to another (as astronomy teaches), is about 29½ days, a table of the new moons for 19 years may be very easily prepared. It is only necessary to observe that this lunar cycle always begins with a year, of which the first new moon falls on the first of January, and that this was the case the first year B. C. Divide by 19 the number of the year plus 1, and the remainder will show what year in the lunar period the given year is. The number of the year is called the *golden number*. Besides these two cycles, which are indispensable for the calculations of the calendar, there are some others, several of them known by the name of *periods*.

The Germans make much use of the word *Cyclus* in science, meaning by it any series of events, works,

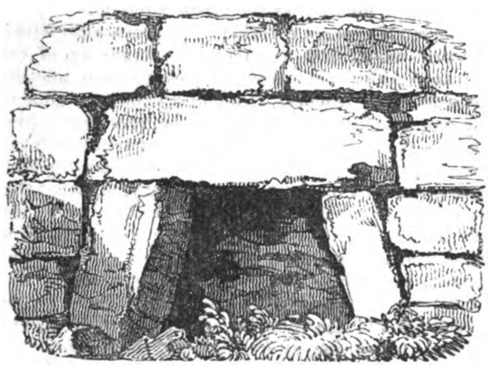
observations, &c., which forms a whole in itself, and reminds us of a circle; thus they speak of the *Cyclus* of works in certain sciences, and *Cyclus* of discoveries by a philosopher, &c., wherever the series forms a well-connected whole.

CYCLOGRAPH, in *practical geometry*; an instrument contrived, as its name imports, for describing the arcs of circles. The simplest kind of cyclograph next to the compasses, is formed of two rulers, so joined together as to be susceptible of standing at any angle between the legs; then by causing the legs or rulers to slide between two pins, while a pencil is fixed at their angular point, the pencil will describe an arc or segment of a circle capable of containing the angle at which the rulers are not.

CYCLOID; the line described by a moving wheel. Imagine a circle which is rolled perpendicularly along a straight line, till the point first at rest is brought to rest again, after an entire revolution. The curve, thus described by this point, is called a *cycloid*, because every point in the circumference of a revolving wheel describes a similar curve. The circle is called the *generating circle*; the line on which it is described, the *base of the cycloid*. The length of the cycloid is always four times the diameter of the generating circle, and its area three times the area of this circle. This line is very important in the higher branches of mechanics.

Imagine a pendulum suspended by a thread, in such a way that, in the swinging of the pendulum between two plates, each of which is bent in the form of a cycloid, the thread rolls and unrolls itself. Then the longest vibrations will be performed in the same time as the shortest, producing an isochronism, and the cycloid is hence called an *isochrone* or *tantochrone*. The name of *brachystochrone* has also been given to the cycloid, because it is the line in which a heavy body, falling in a direction oblique to the horizon, would pass in the shortest time between two points.

CYCLOPEAN WORKS, in *ancient architecture* masonry performed with huge blocks of stone, much of which is to be seen in Sicily, said, by the ignorant, to be the works of an ancient and fabulous gigantic race of people; as Stonehenge is said by the country people to have been built by the devil. Some of these works, called *Cyclopean*, were the walls of Argos and Sicyone. Near to Nauplea, in Argolis, there were caverns which, according to Strabo, were called *Cyclopean*. As servants of Vulcan, the Cyclops were celebrated in mythology and fabulous history for their marvellous works.



A very striking example of Cyclopean architecture exhibited at Stefani, in Sicily, is shown in the engraving, in which a porch is formed of two inclined blocks of eight feet in height, crossed by a third of forty feet in length.

CYDER. See CIDER.

CYLINDER; the name of a geometrical solid, formed by two parallel circular surfaces, called the superior base and the inferior base, and a convex surface terminated by them. There is a distinction between rectangular cylinders and oblique cylinders. In the first case, the axis, that is, the straight line joining the centre of the two opposite bases, must be perpendicular; in the second, the axis must form an angle with the inferior base. The solidity of a cylinder is equal to the product of the base by the altitude. Archimedes found that the solidity of a sphere inscribed in an equilateral cylinder, that is, of a sphere whose diameter is equal to the height, and also to the diameter of the base of the cylinder, is equal to two-thirds of the solidity of the cylinder. The cylinder is one of those figures which are constantly in use for various purposes.

CYLINDROID; a solid resembling the figure of a cylinder; but differing from it as having ellipses for its ends or bases, instead of circles, in the cylinder.

In the cylindroid, the solidity and curve superfices are found the same way as those of the cylinder; viz. by multiplying the circumference of the base by the length or axis; and the area of the base by the altitude, for the solidity.

CYMA, or CYMATIUM, in *architecture*; a member or moulding of the cornice, the profile of which is waved.

CYMBALS, among the ancients; musical instruments consisting of two hollow basins of brass. which emitted a ringing sound when struck together. The brazen instruments which are now used in military music, and have been borrowed by Europeans from the East, seem to have taken their rise from these. The invention of them, according to some writers, must be referred to the worship of Cybele.

DA CAPO, *in music*; an expression written at the end of a movement, to acquaint the performer that he is to return to, and end with the first strain. It is also a call or acclamation to the singer or musician, in theatres or concerts, to repeat a piece which he has just finished.

DACTYLIOTHECA; a collection of engraved gems. The art of engraving gems was nowhere carried to greater perfection than in Greece, where they were worn not only in rings, but in seals, and were much used for other ornamental purposes. The Romans were far behind the Greeks in this art; but they were the first who made collections of precious stones. Scaurus, the son-in-law of Sylla, introduced the custom. Pompey the Great transferred the collection of Mithridates to Rome, and placed it in the capitol. A much larger collection was exhibited by Cæsar in the temple of Venus Genitrix, and, afterwards, under Augustus, by M. Marcellus, in the temple of Apollo Palatinus. In modern times, the princes of Italy vied with each other in collecting these treasures of art.—The family of Gonzaga established the first *dactyliotheca*, and was followed by the family of Este at Modena, that of Farnese, and by Lorenzo de' Medici in Florence. The gems collected by him are marked with *Lor.*, or *Lor. de' M.*, or with *M.* alone. His collection was divided and scattered, but the Medici

established a new one, the foundation of the present *D. Florentina,* the most important existing, as it contains about 4000 gems. Two of the most interesting gems in this collection we have already copied in our mythological articles.

In Rome, collections of no great value were made under Julius II. and Leo X. Piccolomini, a Roman prelate, had the best in that city; and Lucio Odescalchi, afterwards Duke of Bragiani, inherited that of Christina Queen of Sweden. Rome afterwards received the collections of the Vatican (formed more at random than on any concerted plan), of the Barbarini, and of the Strozzi (containing some masterpieces of the art, now in St. Petersburg). The *D. Ludovisia,* belonging to the Prince of Piombino, and that of the Cardinal Borgia at Velletri, famous for its Egyptian gems and *Scarabæi,* are still celebrated.

Naples has beautiful gems in the cabinet at Portici and at Capo di Monte. The prince Piscari formed a collection at Catanea, in Sicily, consisting entirely of gems found in Sicily. In France the first collection was begun by Francis I., but was dispersed in the civil war. In the reign of Louis XIV., Louvois laid the foundation of the present fine collection of antiques in the royal library. The collection of the present king of the French, which he inherited from the Palatinate, is very celebrated. Besides these, there were several private collections of value. The most celebrated in this country are those of the Dukes of Devonshire, Bedford, and Marlborough, and the Earls of Carlisle, and Desborough. Germany also has collections. In the palace of Sans Souci, at Potsdam, near Berlin, several are united, among which is that of Muzel Stosch, rendered famous by the description of Winckelmann. Vienna has a separate cabinet of gems. The collection of Dresden is good. The city library of Leipsic possesses some good gems. The collection at Cashel is extensive, but not very valuable. Munich has some beautiful pieces. There are also many private collections. The cabinet of the king of Holland is valuable.

In the royal palace at Copenhagen, there are some vases inlaid with gems; and Petersburgh has, besides the imperial collection, the foundation of which was that of the engraver Natter, the rich collection of Count Poniatowsky. To multiply elegant and ingenious or remarkable designs on gems, engravings or casts are taken. Thus not only single designs, but all those of the same class, or those of a whole cabinet, are represented by engravings. The impressions of various classes of gems have been collected.

Bellori collected the portraits of philosophers and others; Chifflet, abraxas stones; Gori, gems engraved with stars; Ficoroni, gems with inscriptions; Stosch, gems bearing the names of the artists. Representations of whole collections have been given; as, by Gori, of those contained in the *Museum Florentinum*; by Wicart and Mongez, of those in the gallery of Florence; by Mariette, of the former French collections; by Leblond and Lachaux, of that of the Duke of Orleans; by Eckhel, of that of Vienna. We might also mention the copies of the *Museum d'Odescalchi,* of the cabinets of Gravelle, Stosch, Bossi, and the Duke of Marlborough. But although some of these impressions are very beautiful, the preference ought to be given to the casts. The collections of such casts are also called *dactyliothecæ*; for instance, the *dactyliotheca* of Lippert, consisting of 3000 pieces. Tassie, in London, has executed the largest collection of casts yet known, amounting to 15,000. These are important aids in the study of the branch of antiquities with which they are connected; and many of the finest may now be procured in the streets of the metropolis at the cost of about three shillings for each hundred of casts.

DACTYLIOMANCY; the pretended art of divining by means of rings.

DAIRY; a building appropriated to the purpose of preserving and managing milk, skimming cream, making butter, cheese, &c., with sometimes the addition of pleasure rooms for partaking of the luxuries of the dairy, as syllabubs, cream with fruit, iced creams, &c. See RURAL ECONOMY.

DAL SEGNO. In music, this expression denotes that the singer or player ought to recommence at the former place, where the same mark is put.

DAMASK; an ingeniously manufactured stuff, the ground of which is bright and glossy, with vines, flowers, and figures interwoven. At first, it was made only of silk, but afterwards of linen and woollen, as, for example, damask table-cloth. According to the opinion of some, this kind of weaving was derived from the Babylonians; according to others, invented at a later period, by the inhabitants of Damascus, from which latter place it is thought to have derived its name. The true damasks are of a single colour. If they consist of variegated colours, they are called *ras de Sicile*. The gauze damask also belongs to the silk damask. In modern times, the Italians and Dutch first made damask; and Europe was supplied, as late as the 17th century, from Italy alone, chiefly from Genoa. But the French soon imitated it, and now surpass the Italians. Damask is also brought from India and China, which is very well imitated by the English. At present, damask is made in great quantities in Germany, of three different kinds, Dutch, French, and Italian.

DAMASKEENING, or DAMASKING, the art of inlaying iron or steel with other metals, especially gold and silver, is of great antiquity. It is principally used for sword-blades, guards, cocks of pistols, &c. Herodotus mentions a saucer so ornamented: so, also, were the shields of some of the forces of the Samnites which fought against Rome. It was a favourite manufacture with the ancients. We know not at what time it so flourished at Damascus as to have derived its name from that city.

DAPHNIN; the bitter principle of *Daphne Alpina*. From the alcoholic infusion of the bark of this plant, the resin has been separated by partial evaporation, and the remaining tincture, on being diluted with water and filtered, afforded, on the addition of acetate of lead, a yellow precipitate, from which sulphureted hydrogen disunited the lead, and left the daphnin in small transparent crystals. They are hard, of a grayish colour, a bitter taste; when heated, evaporate in acrid acid vapours; and are sparingly soluble in cold, and but moderately so in boiling water.

DART; a small spear or javelin, much in use among the ancients, and yet seen in many of the more barbarous nations, especially where the use of gunpowder is little known. The Caffrees of South Africa are extremely expert in throwing the dart, as are the aboriginal inhabitants of Australia. The dart in use among the ancients was of two kinds; viz., spear-headed, that is, without barbs; or bearded, like the generality of arrows. The former were often

attached to a long cord, which enabled the thrower to recover his weapon, where it missed the arm, or when it could be withdrawn from a flesh-wound. Most darts have iron heads; but the Americans, particularly in the less frequented tracts of that immense continent, as well as the inhabitants of some parts of Africa, use only a hard wooden staff, sharpened at the point, and a little carbonised by means of fire; others use fish-bones, flints, sea-shells, &c. in their darts, as well as for their arrows. We find the dart to be everywhere very simple, and ordinarily from three to five feet in length.

Datholite, in *mineralogy*. See Natural History Division.

Davit, in a ship; a long beam of timber, used as a crane, whereby to hoist the flukes of the anchor to the top of the bow, without injuring the sides of the vessel as it ascends—an operation which is called, by mariners, *fishing the anchor*.

Day, properly speaking, is the time of a revolution of the earth round its axis (sidereal day, see Sidereal Time); or the time between two passages of the centre of the sun through the same meridian (solar day, see Solar Time)—a time a little differing from the one first mentioned. In common parlance, *day* is opposed to *night*, and signifies the time between sunrise and sunset, or the time during which the sun remains above the horizon. This is called the *natural day*. Thus we have three different days—the natural, the astronomical (reckoned from one culmination to another, or from one moon to another), and the civil day (which is reckoned from midnight to midnight). The 24 hours of the astronomical day are numbered in succession from 1 to 24, whilst the civil day, in most countries, is divided into two portions, of 12 hours each. The first hour, therefore, after midnight, which is one o'clock A. M. of the civil day, makes the 13th hour of the astronomical day, and the first hour of the astronomical day is one o'clock, P. M. of the civil day. The abbreviations P. M. and A. M. (the first signifying *post meridiem*, Latin for *afternoon*; the latter *ante meridiem, forenoon*) are requsite, in consequence of our division of the day into two periods of 12 hours each. In this respect, the mode of numbering the hours from 1 to 24 consecutively has an advantage. If we take a day according to the first definition given of it, its length, of course, is the same throughout the year.

According to the second definition, however, the day, in consequence of the different rapidity of the earth in its orbit, is different at different times, and this difference is uniform throughout the earth; but the time of the natural day is different at the different points of the earth, according to their distance from the equator. The daily apparent revolution of the sun takes place in circles parallel to the equator. If the equator and ecliptic coincided, the circle bounding light and darkness would always divide, not merely the equator, but all its parallels, into two equal parts, and the days and nights would be equal in all the parallels through the year; but at the poles, there would be no night.

Owing to the inclination of the earth's axis to the plane of its orbit (the ecliptic), the parallel of latitude in which the sun appears to move is continually changing; and, therefore, the equator alone (being a great circle) always remains bisected by the circle dividing light from darkness; so that the days and nights here are always equal; while the parallels of latitude, not being great circles, are not equally divided by the circle separating light from darkness, except at the time of the equinox, when the sun is moving in the equator; and, of course, at this time only are the days and nights equal in those parallels.

As you approach the poles, the inequality between the days and nights becomes continually greater, till, at the poles themselves, a day of six months alternates with a night of equal duration. The most distant parallel circles which the sun describes north and south from the equator, are, as is well known, only $23\frac{1}{2}°$ from it. The distance between the polar circles and the poles is the same. Therefore, as a little reflection will show, when the sun is in one of the tropics, all the polar circle in the same hemisphere will be within the illuminated region (because it will be within 90° of the sun) during the whole of a diurnal revolution, while the other polar circle will be in the region of darkness. These circles, therefore, have one day of 24 hours, and one night of the same length, in each year. From the polar circles to the poles, the time of the longest day increases fast, and, in the same measure, the length of the longest night. Notwithstanding the inequality of the periods of light and darkness in the different parts of the earth, each portion of the earth's surface has the sun above its horizon, every year, precisely six months, and below it the same length of time.

Dead-Eye, or Dead Man's Eye; a wooden block, encircled with a rope, or with an iron band, and pierced with three holes through the flat part, in order to receive a rope called the *laniard*, which, corresponding with three holes in another dead-eye, creates a purchase, employed for various uses, but chiefly to extend the shrouds and stays, otherwise called the *standing rigging*.

Dead Reckoning; the judgment or estimation which is made of the place where a ship is situated, without any observation of the heavenly bodies. It is obtained by keeping an account of the distance which the ship has run by the log, and of her course steered by the compass, and by rectifying these data by the usual allowances for drift, lee-way, &c., according to the ship's known trim. This reckoning is, however, always to be corrected as often as any good observation of the sun can be obtained.

Deaf and Dumb. See Dumb.

Deal; a thin kind of fir planks, of great use in carpentry: they are formed by sawing the trunk of a tree into a great many longitudinal divisions, of more or less thickness, according to the purposes they are intended to serve. Deals are rendered much harder by throwing them into salt water as soon as they are sawed, keeping them there three or four days, and afterwards drying them in the air or sun; but neither this nor any other method yet known will preserve them from shrinking. Deals are imported into this country from Christiana, and other parts of Norway; from Dantzic, and other parts of Prussia; from St. Petersburg, Archangel, Narva, Memel, &c. They are sold by the piece or by the standard hundred, or by the long hundred of 120. A standard, or reduced deal, is one inch and a half thick, eleven inches wide, and twelve feet long.

Death, in common language, is opposed to *life*, and considered as the cessation of it. It is only, however, the organic life of the individual which becomes extinct; for neither the mind nor the matter which constituted that individual can perish

That view of nature which considers the whole as pervaded throughout by the breath of life, admits only of changes from one mode of existence to another. This change, which is called *death*, does not take place so quickly as is generally believed. It is usually preceded and caused by disease or the natural decay of old age.

The state called *death* takes place suddenly only when the heart or the brain is injured in certain parts. Probably the brain and the heart are the parts from which, properly speaking, death proceeds; but, as the cessation of their functions is not so obvious as the cessation of the breath, which depends on them, the latter event is generally considered as indicating the moment when death takes place. In the organs of sense and motion, the consequences of death first become apparent; the muscles become stiff; coldness and paleness spread over the whole body; the eye loses its brightness, the flesh its elasticity; yet it is not perfectly safe to conclude, from these circumstances, that death has taken place, in any given case, because experience shows that there may be a state of the body in which all these circumstances may concur, without the extinction of life. This state is called *asphyxia*. The commencement of putrefaction, in ordinary cases, affords the first certain evidence of death. This begins in the bowels and genitals, which swell, become soft and loose, and change colour; the skin, also, begins to change, and becomes red in various places; blisters show themselves; the blood becomes more fluid, and discharges itself from the mouth, nose, eyes, ears, and anus. By degrees, also, the other parts are decomposed, and, last of all, the teeth and bones.

In the beginning of decomposition, azote and ammonia are produced: in the progress of it, hydrogen, compounded with carbon, sulphur, and phosphorus, is the prevailing product, which causes an offensive smell, and the light which is sometimes observed about putrefying bodies. At last, only carbonic acid gas is produced, and the putrefying body then smells like earth newly dug. A fat, greasy earth remains, and a slimy, soap-like substance, which mixes with the ground, and contributes, with the preceding decompositions, to the fertility of it. Even in these remains of organized existence, organic life is not entirely extinct; and they contribute to produce new vegetable and animal structures. Putrefaction is much influenced by external circumstances, particularly air, heat, and water. When the body is protected from the action of such agents, it changes into *adipocire;* but this process requires a much longer time than common putrefaction.

In very dry situations, the body is converted into a mummy, in which state bodies are found in the arid deserts of Africa, and on the mountains in Peru. Some vaults are remarkable for preserving corpses from putrefaction. It is well known to every reader, that particular substances counteract putrefaction; for instance, those used in tanning, and in embalming mummies, and more especially the chlorides.

Death, agony of, is the state which immediately precedes death, and in which life and death are considered as struggling with each other. This state differs according to the cause producing it. Sometimes it is a complete exhaustion; sometimes a violent struggle, and very irregular activity, which, at last, after a short pause, terminates in death.

In some cases, consciousness is extinguished long before death arrives; in other cases, it continues during the whole period, and terminates only with life. The person in this condition has already somewhat the appearance of a corpse; the face is pale and sallow, the eyes are sunken, the skin of the forehead is tense, the nose pointed and white, the ears are relaxed, and the temples fallen in; a clammy sweat covers the forehead and the extremities, the alvine discharges and that of the urine take place involuntarily, the respiration becomes rattling, interrupted, and, at length, ceases entirely. At this moment, death is considered to take place. This state is of very different length; sometimes continuing for minutes only, sometimes for days. When the patient is in this condition, nothing should be attempted but to comfort and soothe him by prayer, by consoling assurances, by directing his attention to his speedy union with departed friends.

As long as the dying person is able to swallow, wine or other cordials may be given from time to time. It is a grateful duty to minister to the sufferings of those we love; and, where there is no hope, these offices have the additional interest that they are the latest we can pay. We have described how the violent struggle preceding death manifests itself, particularly on the human face, that tablet of all expression. After death, however, it not unfrequently happens that the countenance regains its most natural expression, and the saying is common —"How natural, how like himself!" The mind seems for a moment to have regained its influence over what it has so long irradiated, and to shed over the countenance its most beautiful light, to cheer the hearts of the friends who have witnessed the distortion of death, and afford an earnest of its own immortality.

Death, Dance of; an allegorical picture, in which are represented the various figures and appearances of death in the different relations of life, as a dance, where Death takes the lead. The idea of such a dance appears to be originally German, and to belong to poetry. In later times it was used also in England and France, by poets and artists. The French have such a dance (*La Danse Macabre*), derived, it is said, from a poet called Macaber, but little known. A Dance of Death was painted on the walls of the church-yard of the Innocents, at Paris, about the middle of the 15th century, which the chapter of St. Paul's, in London, caused to be copied, to adorn the walls of its monastery. Gabriel Peignot, in the *Recherches sur les Danses des Morts et sur l'Origine des Cartes à jouer*, investigated the origin of the Dance of Death in France, and thus explained the dancing positions of the skeletons: that, according to the relations of old chronicles, those who were attacked by the plague ran from their houses, making violent efforts to restore their rapidly-declining strength by all kinds of morbid movements. Others derive the origin of this representation from the masquerade. These dances are often found painted on the walls of Catholic burial-places. The most remarkable Dance of Death was painted, in fresco, on the walls of the church-yard, in the suburb of St. John, at Basle, which was injured, in early times, by being washed over, and is now entirely destroyed. This piece has been ascribed to the celebrated Hans Holbein; but it has long since been proved that it existed 60 years before his birth. It was painted at

Basle, in the year 1431, by an unknown artist, in commemoration of the plague, which prevailed there at that time; the council was then sitting, and several of its members were carried off by it. It represented Death as summoning to the dance persons of all ranks, from the pope and the emperor down to the beggar, which was explained by edifying rhymes. That piece contained about 60 figures, as large as life. Besides being ascribed to Holbein, as was before stated, it has also been ascribed to a painter named Glauber, but without foundation. Holbein perhaps conceived, from this picture, the idea of his Dance of Death, the original drawings of which are in the cabinet of the Empress of Russia, Catharine II. Some say that Holbein himself made the wood-cuts of it. The latest engravings of this picture of Holbein are in 33 plates, in the *Œuvres de Jean Holbein, par Chr. de Meckel* (1st volume, Basil, 1780). Similar representations were painted, in the 15th century, in other cities of Switzerland. The Dance of Death in St. Mary's Church, at Lubeck, was completed in 1463. On the walls of the church-yard of the Neustadt of Dresden, there is, even at the present time, to be seen a similar Dance of Death. It is now, however, somewhat indistinct and consists of 27 *bassi-relievi* figures, worked on sand-stone, and includes persons of both sexes, and of all ranks. The labour of the sculptor has more merit than the unpoetical rhymes which were afterwards added.

December, the twelfth month of our year, from the Latin *decem* (ten), because, in the Roman year instituted by Romulus, it constituted the tenth month, the year beginning with March. In December, the sun enters the tropic of Capricorn, and passes our winter solstice. This month was under the protection of Vesta.

Decimal Arithmetic; a kind of calculation in which no other fractions are used than tenths, hundreths, thousandths, &c., which are consequently called *decimal fractions*. Joh. Regiomontanus first made use of it in his Tables of the Sines. It affords great facilities in calculation. As, in our system of notation, the values of figures are determined by their places, so that the figure on the left is always of ten times more value than the next at the right hand; so in decimal fractions, which must be considered as an extension of the decimal system, the place of the numerator determines the value of the denominator of the fraction, which need not, therefore, be expressed. The integers are separated from the fractional numbers by a period, so that this period, placed between several numbers, is the characteristic sign of a decimal fraction. For instance, 5.36 is 5 whole numbers, 3 tenths and 6 hundredths, or 36 hundredths; 5.009 is 5 whole numbers and 9 thousandths. If the divisions of money and measures be in a decimal ratio, as is the case with those adopted during the French revolution, the ease of calculation is greatly increased, almost all operations being reduced to addition and subtraction.

Decimal Measure; the division of the unit of measure (whatever it be, as a foot, a rod, &c.) into ten equal parts. The quadrant of a circle has also been divided into ten equal parts. In this case, the tenth part of such a quadrant is called a *decimal degree*. The French mathematicians, however, call the hundreth part of such a quadrant a *decimal degree*, and the hundreth part of such a degree a *decimal minute*.

Decked, in *heraldry*; a term applied to an eagle, or other birds, when their feathers are trimmed at the edges with a small line of another colour.

Declination of a Planetary Body, is its distance from the equinoctial, northward or southward. When the sun is in the equinoctial, he has no declination, and enlightens half the globe from pole to pole. As he increases in north declination, he gradually shines farther over the north pole, and leaves the south pole in darkness. In a similar manner, when he has a south declination, he shines over the south pole, and leaves the north pole in darkness.—23° 28′ is the sun's greatest declination north or south.

Declinator, or Declinatory; an instrument contrived for taking the declinations, inclinations, and reclinations of planes.

Decline; a popular term for almost all chronic diseases, in which the strength and plumpness of the body gradually decline, or decrease, until the patient dies. The term is synonymous with consumption (which see), and is more particularly applied to consumption of the lungs, when the blood ceases to receive a due oxygenating power from the vital principle of the air. Counter-irritants appear to have had the happiest effects, even in the hands of the most ignorant pretenders to the medical art, and, there is little doubt but that, in the hands of a discriminating practitioner, a series of blisters, united to a proper regimen, will accomplish much in all the earliest stages of consumption.

Decoction, in *pharmacy*; a very common and highly useful way of extracting the soluble and efficacious part of many drugs, particularly of barks, woods, and roots, and other substances which contain much inert and insoluble matter. The proportion of the substance boiled in the water seldom, if ever, exceeds an ounce of the former to a pint of the latter, and frequently half or a quarter of an ounce is sufficient.

Decomposition, Chemical, is the resolution of a compound substance into its constituent parts, which are exhibited either separate or in some new combination. The compounds which are spontaneously formed by organic bodies, both vegetable and animal, are of a different nature from those which exist in unorganized matter. They are the peculiar results of vital processes, and neither their structure nor composition can be imitated by art.

During life, the elements of organic bodies are held together by vital affinities, under the influence of which they were originally combined. But no sooner does life cease, than these elements become subject to the laws of inert matter. The original affinities, which had been modified or suspended during life, are brought into operation; the elementary atoms re-act upon each other, new combinations are formed, and the organized structure passes, sooner or later, into decay. The rapidity with which decomposition takes place in organic bodies, depends upon the nature of the particular substance, and upon the circumstances under which it is placed. Temperature, moisture, and the presence of decomposing agents, greatly affect both the period and extent of this process. By regulating or preventing the operation of these causes, the duration of most substances may be prolonged, and many materials are rendered useful, which, if left to themselves, would be perishable and worthless. The preservation of timber, of fibrous

substances, of leather, of food, and of various objects of art, is a subject of the highest importance, and has received, at various times, much attention from scientific experimentalists. See GALVANIC ELECTRICITY, MANURES, and VEGETABLE LIFE.

DECOY, in *military* affairs; a stratagem to carry off the enemy's horses in a foraging party, or from pasture. The word is also used to denote a stratagem employed by a small ship-of-war, to betray a vessel of inferior force into an incautious pursuit till she has drawn her within the range of her cannon. It is usually performed by painting the stern and sides, in such a manner as to disguise the ship, and represent her either much smaller, and of inferior force, or as a friend to the hostile vessel, which she endeavours to ensnare, by assuming the emblems and ornaments of the nation to which the stranger is supposed to belong.

DECREPITATION is the crackling noise, accompanied by a violent exfoliation of their particles, which is made by several salts and earthy compounds, on being suddenly exposed to heat. It appears to be referable to the same cause which occasions the cracking of glass and cast-iron vessels, when they are incautiously heated; viz., the unequal expansion of the *laminæ* which compose them, in consequence of their imperfect power of conducting heat.

DECRESCENDO; an Italian term in music, which denotes the gradual weakening of the sound.

DECUSSATION; a term in geometry, optics, and anatomy, signifying the crossing of two lines, rays, or threads, when they meet in a point, and then go on separately from one another.

DEEP SEA LINE, or DIP SEA LINE, in *nautical* language, a small line used for sounding, when a ship is in very deep water at sea. At the end of this line is a piece of lead called the deep sea lead, at the bottom of which is a coat of white tallow, to bring up stones, gravel, shells, or the like, from the bottom, in order to learn the difference of the ground; which being entered, from time to time, in the seaman's books, by comparing of observations, enables them to guess by the soundings, &c. what coast they are on, though they cannot see the land.

DEFILE; a narrow way, admitting only a few persons abreast. The term is often erroneously confined to mountain passes. As they delay the march of troops, and expose them to the fire of the enemy, they must be avoided if possible, particularly by artillery and waggons.

A defile is defended in different ways. When it is formed by heights (particularly if they are covered with wood), it is advisable to occupy the entrance, and station the troops *en masse* behind: when this is not the case, the best way will be to render the passage as impracticable as possible, and to make a stand behind the outlet of the defile, so that the enemies advancing from it may be checked by an effectual fire, and prevented from developing themselves. A position before the defile, for the purpose of defending it, is only to be thought of when the passage of another division is to be covered. This method may be more or less varied in the defence of bridges. In passing a defile in sight of the enemy, after the usual precautions of patrols, &c., the van-guard must first march rapidly through, and take a position before the outlet, so as to cover the developement of the succeeding masses, the preventing of which will be the object of the enemy. To defile is, therefore, to pass through a narrow passage. To march before any one with a narrow front, that is, *en colonne*, or by files, is also called *defiling*.

DEFENCES, in *heraldry;* the weapons of any beast, as the horns of a stag, the tusks of a wild boar, &c.

DEGREE, in *algebra;* a term applied to equations, to distinguish the highest power of the unknown quantity. Thus, if the index of that power be 3 or 4, the equation is respectively of the 3d or 4th degree.

DEGREE, in *geometry* or *trigonometry*, is the 360th part of the circumference of any circle; every circle being considered as divided into 360 parts, called degrees, which are marked by a small ° near the top of the figure; thus, 45° is 45 degrees. The degree is subdivided into 60 smaller parts, called *minutes;* the minute into 60 others, called *seconds;* the second into 60 *thirds*, &c. Thus 45° 12′ 20″ is 45 degrees, 12 minutes, 20 seconds. The magnitude or quantity of angles is estimated in degrees; for, because of the uniform curvature of a circle in all its parts, equal angles at the centre are subtended by equal arcs, and by similar arcs in peripheries of different diameters; and an angle is said to be of so many degrees as are contained in the arc of any circle comprehended between the legs of the angle, and having the angular point for its centre. Thus we say "an angle of 90°," or "of 45° 24′." It is also usual to say, "such a star is elevated so many degrees above the horizon," or "declines so many degrees from the equator;" or "such a town is situated in so many degrees of latitude or longitude." A sign of the ecliptic or zodiac contains 30 degrees.

Degree of Latitude is the space or distance on the meridian, through which an observer must move to vary his latitude by one degree, or to increase or diminish the distance of a star from the zenith by one degree; and which, on the supposition of the perfect sphericity of the earth, is the 360th part of the meridian. The length of a degree of a meridian, or other great circle on the surface of the earth, is variously determined by different observers, and the methods made use of are also various; and therefore without entering into the history of all attempts of this kind, we shall present our readers with the following

Table of the different Lengths of a Degree, as measured in various Parts of the Earth, the Time of its Measurement, the Latitude of its middle Point, &c.

Date.	Latitude.			Extent in Eng. miles & decimals.	Measurers.	Countries.
1525	49°	20½′	N.	68.763	M. Fernel	France.

Ellipticities of the Earth, expressed in Parts of its equatorial Diameter.

Authors.	Ellipticities.	Principles.
Huyghens . . .	$\frac{1}{578}$	Theory of gravity.
Newton	$\frac{1}{230}$	
	$\frac{1}{174}$	
Maupertuis, &c.	$\frac{1}{126}$	Mensuration of arcs.
	$\frac{1}{213}$	
Swanberg . . .	$\frac{1}{323.5}$	
Clairaut	$\frac{1}{177.33}$	Rotatory motion.
	$\frac{1}{337}$	Vibrations of the pendulum.
Treisnsoker . .	$\frac{1}{319}$	Occultations of the fixed stars.
Laplace	$\frac{1}{331}$ $\frac{1}{306}$	Precession, nutation, pendulum, theory of the moon, &c.

Degree of Longitude is the space between two meridians that make an angle of 1° with each other at the poles, the quantity or length of which is variable, according to the latitude. The following table expresses the length of a degree of longitude in different latitudes, supposing the earth to possess a perfect sphericity :—

Deg. Lat.	English miles.	Deg. Lat.	English miles.	Deg. Lat.	English miles.	Deg. Lat.	English miles.	Deg. Lat.	English miles.
0	69.07	19	65.24	38	54.37	57	37.58	76	16.70
1	69.06	20	64.84	39	53.62	58	36.57	77	15.52
2	69.03	21	64.42	40	52.85	59	35.54	78	14.85
3	68.97	22	63.97	41	52.07	60	34 50	79	13.17

Degrees, Measurement of. After Sir Isaac Newton had taught that the earth, on account of its motion round its axis, must be highest near the equator, and that the diameter of the equator must be longer, by one 230th part, than the diameter from pole to pole, the French wished to investigate the subject farther by actual measurement. Newton gave them warning that the difference between a degree at Bayonne and one at Dunkirk was so trifling that it could not be detected at all with the imperfect instruments then in use; and was, in fact, afraid that they might come to a result directly opposite to what he conceived to be correct, and bring confusion into science. But his warnings were of no avail. The measurement was begun, and the fear of the great philosopher was realized; for the result was, that the axis of the poles was longer than a diameter of the equator, and that the earth was, in form, more like a lemon than an orange. For 40 years, disputes were maintained on this point, without settling the question; and, at last, the Academy of Sciences resolved, on the proposition of Condamine to have a degree measured at the equator (the expedition went to South America in 1735), and one in Lapland (Kittis and Tornea being the extreme stations to which the expedition was sent in 1736). It was found that the northern degree was greater than that under the equator, and that Newton's conjecture was right. But the question still remained, How great is the flattening of our planet? The theory said, one 230th part, if the earth had been in a perfectly liquid state, when it began its rotation. The calculations, however, always gave different results, varying according to the different measurements adopted as the basis of them; for measurements had been made, not only in America and Lapland, but also in France, England, Hungary, and Italy. It was concluded, that the earth was not a regular body, but had great local inequalities. Though this was possible, yet the conclusion was too hasty, because these supposed inequalities might be caused by the insufficiency of the instruments, and by the smallness of the arcs measured.

When the French established their new and admirable system of measures and weights upon the basis of the metre, which was to be the ten millionth part of the distance from the equator to the pole (3$\frac{128}{1000}$ English feet; see Measures), it was necessary to know, with accuracy, the circumference and the flattening of the earth. A measurement took place in France, not of one degree, but of ten degrees, from Dunkirk to Formentera. In Sweden, in 1802, the degree, which, 80 years before, had been measured by Maupertuis, was now measured again, with better instruments, and thus the circumference and flattening of the earth were pretty well ascertained.

After the peace, the measurements of degrees, which were made in England, under General Roy, by Lieutenant-colonel Mudge, were connected with those in France; and thus an arc of 20 degrees, from the Balearic Islands, near the coast of Spain, over France and England, to the Orcades, has been measured, and the flattening of the earth has been determined as accurately as it can be done in Europe. The flattening has been found to be one 304th. In India, Lambton has begun the measurement of a degree.

These measurements of degrees are among those enterprises which do mankind much honour, because they are not undertaken for the sake of immeditate profit, nor of bare utility, but from an ardent desire of knowing the truth, from the same deep thirst for knowledge, which has so often impelled men to explore the icy seas of the poles and the burning deserts of Africa.

The degrees of longitude are largest under the equator, and diminish continually towards the pole. Under the equator, a degree of longitude contains 60 geographical, 69½ statute miles. If the form of the earth is not entirely regular, the degrees of longitude on the same parallel of latitude cannot all be of the same length, and it has been proposed to investigate this by actual measurement. This task is, in the trigonometric part, as easy as the measurment of a degree of latitude; but in the astronomical part, it is 15 times more difficult.

The difference of the longitude of two places is determined by the difference of the hour of the day, at the same point of time in the two; as a place, situate 15 degrees to the east of another, has noon a whole hour earlier. One hour, therefore, corresponds to 15 degrees, or 1042½ statute miles under the equator, or 5,504,400 feet; a minute of time, to 91,740 feet, and

a second of time, to 1529 feet. A mistake of a second of time, therefore, in calculating the longitude of two places, makes a corresponding error in space. To determine time, within two or three seconds, by means of rockets, at a distance of 1042½ miles, is impossible; and, whilst the measurement of an arc, corresponding to this distance, trigonometrically, may be attended with an error to the amount of 200 feet, an astronomical measurement would leave an uncertainty of 2000 feet. The earlier measurements of the French were directed, in the North, by Maupertuis; in the South, by Bouguer.

The latest information respecting this subject is given by Captain Edward Sabine. He made observations with the pendulum, from lat. 13° S. to lat. 80° N. He calculates the flattening of the earth to be $\frac{1}{288.4}$; and if the measurements of Sabine, Kater, and the modern French ones by Biot, are connected, and the mean of the whole taken, the flattening will be found to be $\frac{1}{288.1}$.

Delft-Ware is a kind of pottery covered with an enamel or white glazing, which gives it the appearance and neatness of procelain. Some kinds of this enamelled pottery differ much from others, either in sustaining sudden heat without breaking, or in the beauty and regularity of their forms, of their enamel, and of the painting with which they are ornamented. In general, the fine and beautiful enamelled ware, which approaches the nearest to procelain in external appearances, is that which least resists a brisk fire. Again, those which sustain a sudden heat are coarse, and resemble common pottery. This kind of ware has its name from Delft, in Holland, where it is made in large quantities.

Deltoides, in *anatomy;* one of the large muscles of the arm, so called, because its form is triangular, and therefore resembles that of the capital delta of the Greek alphabet.

Demonstration, in *military* language; a movement towards any place, for the purpose of deceiving the enemy, and concealing the true design.

Denarius. This term was applied by the Romans both to a coin and a weight. As a coin, it was equal to two asses. When the term was employed with reference to weight, it equalled $\frac{1}{96}$ part of the pound. The term is not now employed in France, but was formerly used for 63 grains.

Denominator, in *arithmetic;* a term only used in speaking of fractions, or broken numbers. The denominator of a fraction, is the number, or letter below the line; showing into how many parts the integer is supposed to be divided by the fraction.—Thus in the fraction $\frac{7}{12}$ the number 12 is the denominator, and shows that the integer is here divided into 12 parts.

Density, strictly speaking, denotes vicinity or closeness of particles; but in mechanical science, it is used as a term of comparison, expressing the proportion of the number of equal *moleculæ*, or the quantity of matter in one body, to the number of equal *moleculæ* in the same bulk of another body. Density, therefore, is directly as the quantity of matter, and inversely as the magnitude of the body. Since it may be shown experimentally, that the quantities of matter, or the masses in different bodies, are proportional to their weight; of consequence, the density of any body is directly as its weight, and inversely as its magnitude; or the inverse ratio of the magnitudes of two bodies, having experimentally equal weight (in the same place), constitutes the ratio of their densities. No body is absolutely or perfectly full of matter, so as to have no vacuity or interstices: on the contrary, it is the opinion of Newton, that even the densest bodies, as gold, &c., contain but a small portion of matter, and a great portion of vacuity; or that they contain a great deal more pores or empty space than real substance.

Density of the Earth. The determination of the density of the earth, as compared with that of water, or any other known body, is a subject which has excited considerable interest amongst modern mathematicians; and nothing can, at first sight, seem more beyond the reach of human science, than the due solution of this problem; yet this has been determined, and on such principles, that, if it be not correctly true, it is, probably, an extremely near approximation. The first idea of determining the density of the earth was suggested by M. Bouguer, in consequence of the attraction of Chimborazo, which affected his plumb-line while engaged with Condamine, in measuring a degree of the meridian, near Quito, in Peru. This led to the experiments on the mountain Schehallien, in Scotland, which were carried on under the direction of Dr. Maskelyne, and afterwards submitted to calculation by Dr. Hutton, who determined the density of the earth to be to that of water as 4½ to 1. But in consequence of the specific gravity of the mountain, being assumed rather less than it ought to have been, the above result is less than the true density, as has since been shown by Doctor Hutton and Professor Playfair, the former of whom makes it, in his corrected paper, as 99 to 20, or nearly as 5 to 1. The same problem has been attempted on similar principles, but in a totally different manner, by the late Mr. Cavendish, who found the density of the earth to be to that of water, as 5.48 to 1. Taking a mean of all these, we have the density of the earth to that of water, as 5.24 to 1, and which, as we before observed, is probably an extremely near approximation.

Dentifrice; a preparation for cleaning the teeth, of which there are various kinds. The best dentifrice is the carbon of grape stalk, or the stem of the grape vine converted into charcoal. Dilute sulphuric acid will immediately render them white, but it is highly injurious to them.

Dephlogisticated Air. See Oxygen.

Descant, in *music;* the art of composing in several parts. It is of three kinds, namely, plain, figurative, and double. *Plain descant* is the ground-work of all compositions, consisting altogether in the orderly placing of many concords answering to counter-point. *Figurative descant* is that wherein discords are concerned as well as concords; and this properly may be denominated the ornament, or rhetorical part of music. For in this are introduced all the varieties of points, fuges, syncopes, or bindings, diversity of measures, intermixtures of discordant sounds, or whatever else art and fancy can exhibit, which set forth and adorn the composition; whence it is named florid, or figurative descant. *Double descant* is so called when the parts are so contrived, that the treble may be made the bass, and the bass the treble.

Descension, in *astronomy*, is either right or oblique. Right descension is an arch of the equinoctial, intercepted between the next equinoctial point and the intersection of the meridian, passing through the centre of the object, at its setting, in a right sphere.

Oblique descension, an arch of the equinoctial, intercepted between the next equinoctial point and the horizon, passing through the centre of the object, at its setting, in an oblique sphere.

DESIGN. See DRAWING.

DESSICATION, in *chemistry*, is the act of reducing any substance to perfect dryness, and is an operation the accuracy of which is of very great importance, as the estimation of weights and quantities is materially affected by it.

DETACHMENT, in *military* affairs; a certain number of soldiers drawn out from several regiments or companies equally, to be employed as the general thinks fit, either on an attack, at a seige, or in parties for to scour the country. A detachment of two or three thousand, is a command for a brigadier; eight hundred for a colonel; four or five hundred for a lieutenant-colonel. A captain never marches on a detachment with less than fifty men, a lieutenant, an ensign, and two serjeants. A lieutenant is allowed thirty men and a serjeant; and a serjeant ten or twelve men. Detachments are sometimes made of entire squadrons and battalions.

DETONATION, in *chemistry;* an explosion with noise, made by the inflammation of a combustible body. Decrepitation differs only as producing a fainter noise, or merely a kind of crackling sound peculiar to certain salts. Fulmination is a more quick and lively detonation, such as takes place with certain preparations of gold, silver, mercury, &c.

DETRANCHE, in *heraldry;* a line bendwise, proceeding always from the dexter side, but not from the very angle, diagonally athwart the shield.

DEVICE, in *heraldry;* a name common to all figures, ciphers, characters, rebuses, mottoes, &c., which, by their allusions to the names of persons, of families, &c., denote their qualities, nobility, or the like. Device, in this sense, is of a much older standing than heraldry itself; being that which first gave rise to armorial ensigns. Thus the eagle was the device of the Roman empire. S. P. Q. R. was the device of the Roman people, and still continues to be what is called the escutcheon of the city of Rome. The first devices were mere letters placed on the borders of liveries, housings, and banners, and at length on shields. Thus the C was the device of the French kings of the name of Charles, from Charles V. to Charles IX.

Badges, impresses, and devices were greatly in use in England, from the reign of King Edward I. until that of Queen Elizabeth, when they sunk into disuse. *Device* is now taken in a more limited sense, for an emblem, or a representation of some natural body, with a motto, or sentence, applied in a figurative sense. Thus a young nobleman of great courage and ambition, bore for his device, in a carousal at the court of France, a rocket mounted in the air, with this Italian motto, *Poco duri, purchè m'innalzi* (May I continue but a short time, provided I mount high). A device is, therefore, a painted metaphor. Devices are used on coins, counters, seals, shields, triumphal arches, artificial fire-works, &c. The French have distinguished themselves in the invention of devices, especially since the time of Cardinal Mazarin, who had a great fondness for them. The Italians have reduced the making of devices to an art, and laid down laws and rules for this purpose.

DEW; a phenomenon in nature, which begins to be deposited about sun-set, and is most abundant in valleys and plains near rivers, and other collections of waters, and abounds on those parts of the surface which are clothed with vegetation. It is often suspended when rain is approaching, in windy weather, and before thunder-storms. Its approach, in the extensive valley watered by the Thames, presents the following appearance:—After a clear warm day, there is gradually formed on the horizon a continuous haze, rising sometimes to a considerable height, and often tinged by the setting sun with a fine gradation of red and violet shades. This is the precipitated water, become faintly visible in its descent. Dew is always to be found on the grass by the time that this haze has become conspicuous, and its abundance is proportioned to the density and permanence of the latter. The quantity of dew deposited, differs considerably at different places, and at different seasons in the same place; nor does it fall upon bodies indiscriminately. In explanation of these phenomena, several hypothesis have been suggested, which we have not room to describe; but no theory has yet been established which is quite satisfactory. Upon the whole, however, the obvious and true reason of the formation of dew is, that part of the vapours which are raised in the course of the day by the heat of the sun, and remain floating in the air, are condensed by the cold of the night, and settle upon different bodies; but from various peculiarities which have been observed in the dew, it has been inferred that this is not the cause of its formation. The readiness with which dew falls upon glass, porcelain, and a few other bodies, that are non-conductors of electricity, and the difficulty with which it attaches itself to metallic bodies, which are the best conductors of electricity (see ELECTRICITY), has given reason to suspect that electricity is concerned in the production of this phenomenon; and this opinion is corroborated by the well-ascertained fact, that vapour contains more of electricity than the water from which it originates. In addition to which, it must be recollected, that certain bodies are much better conductors of heat than others, and in general the best conductors of heat are the best conductors of electricity. Hence, it seems more than probable, that the formation of dew, with all its peculiarities, depends upon various causes, which tend to vary the effects according as any one of them happens to preponderate.

In this island the dew is observed (like the drops of a misling rain, upon the leaves of grass and other vegetables, upon wood, glass, porcelain, &c., or upon the earth, which is thereby frequently rendered sensibly moist) more copiously in spring and summer mornings, than at any other times of the year. In autumn, however, and even in winter, it frequently happens that an abundant dew is deposited in the course of the night. In countries situated near the equator, the dews are generally observed in the morning throughout the whole year; and in some places in the east, where rain seldom falls, they are so copious, as in a great measure to supply its deficiency.

DEXTER, in *heraldry*, is applied to the right side, as sinister is to the left. The word is pure Latin, signifying right-handed; whence the word dexterity, for address and ability in the performing of any thing.

DEXTROCHERE, in *heraldry*, is applied to the right arm painted on a shield, sometimes naked, sometimes clothed, or adorned with a bracelet, and

sometimes armed, or holding some moveable, or member used in the arms. The dextrochere is sometimes placed as the crest.

Diacoustics, also called *diaphonics*, is the name of the subject of refracted sound, or that branch of acoustics which considers the passage of sound through different mediums. (See Acoustics).

Diaglyphon, in ancient *sculpture;* the name by which the Greeks designated works in sculpture when sunk in with the chisel. Among the most celebrated of these were the buckler and pedestal of a colossal statue of Minerva at Athens. When it was in relief, the work was called *anaglyphic*.

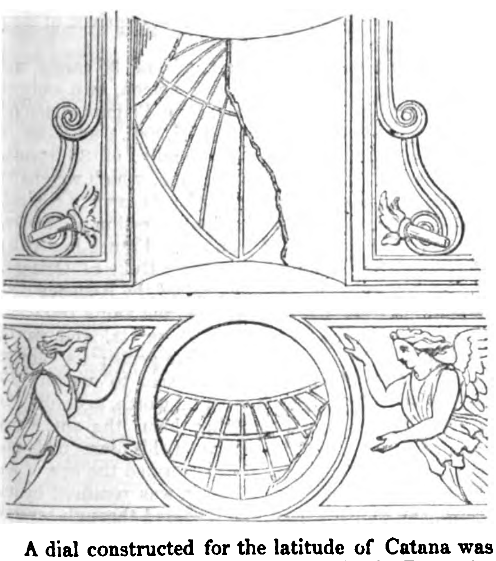
Diagnosis, in *medicine;* the distinction of one disease from others resembling it, by means of a collected view of the symptoms.

Diagnostic symptoms are the leading symptoms, or those which are most characteristic of any particular form or seat of disease.

Diagonal, Diagonal Line; a straight line, joining two angles not adjacent, in a rectilinear figure, having more than three sides. Every rectilinear figure may be divided by diagonals into as many triangles as it has sides, *minus* two.

Diagram; a figure or geometrical delineation, applied to the illustration or solution of geometrical problems, or a description or sketch in general. Anciently, it signified a musical scale. Among the Gnostics, the name *diagram* was given to a figure formed by the superposition of one triangle on another, and inscribed with some mystical name of the Deity, and worn as an amulet.

Dial, Sun. This instrument has been known from the earliest times: the Egyptians, Chaldeans, and Hebrews (*Isaiah* xxxvii. 8) were acquainted with the uses of it. The Greeks derived it from their eastern neighbours, and it was introduced into Rome during the first Punic war. One of the earliest that has been preserved was discovered in the ruins of Herculaneum during the excavations at that place, and it appears to have consisted of a double dial, one portion being formed like a shield, and the other exactly circular.

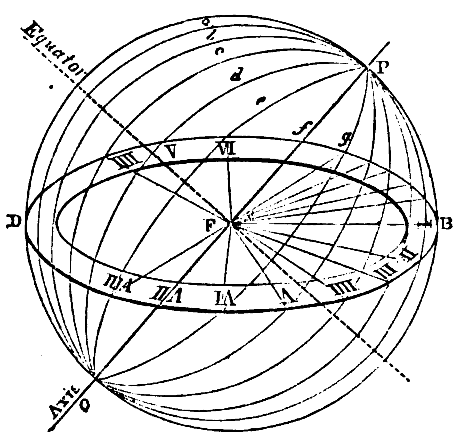


A dial constructed for the latitude of Catana was carried off from that city and placed in the Forum by Valerius Messana; but, as there was a difference of 40° of latitude between the two cities, it could not, of course, indicate the true time at Rome. Before this period, the Romans ascertained the hour by the rude method of observing the lengths of shadows, or, in the absence of the sun, by the clepsydra, which a slave was employed in tending. Sun-dials have lost much of their value in modern times, by the general introduction of instruments which indicate the time at any period of the day or night; but clocks and watches require to be regulated, and the shadows projected by the sun are the most convenient standard for this purpose. Dials are of various kinds; but the horizontal and vertical are most commonly used. In this place, we can give only the general rules of construction applicable to all of them. Suppose 12 planes, making with each other angles of 15°, passing through the axis of the earth and dividing the sphere into 24 equal parts, one of these planes being the meridian of the place of the observer; commence from the meridian, and, moving towards the west, number these planes respectively 1, 2, 3, and so on up to 12, which will be the lower meridian of the place; commencing from this point, number as before, 1, 2, 3, &c., again to 12, which will now fall on the upper meridian. We shall thus have a series of horary circles, in passing from one of which to the next, the sun will occupy one hour. At noon, he will be on the meridian, which is numbered 12; it is then 12 o'clock; an hour before, he was on the last horary circle preceding (to the east), numbered 11, and it was 11 o'clock. Twelve hours from the time of passing the upper meridian, he will pass the lower, also numbered 12, and it will be midnight. Suppose, now, an opaque plane passing through the centre of the earth, and intersected by the 12 planes in as many diverging straight lines, and mark these lines with the numbers belonging to their respective planes. This opaque plane will represent the face of a dial, the straight lines will form the horary lines marked on its surface, and the style will represent the axis of the earth, and will project its shadow successively on each of the hour lines, the number affixed to which will show the hour of the day; that is, at 10 o'clock the shadow will fall on the line numbered 10, &c.

We shall thus have a dial constructed at the centre of the earth; but the radius of the earth, or the distance from its centre to its surface, is so small, in comparison with the distance of the earth from the sun, that it may be considered as nothing: we may, therefore, transport our central dial to any given place, keeping the style and surface always parallel to the positions in which we supposed them at first, and we shall have a dial for that place. This is the theory of dials. It follows, from this explanation, 1. that a sun-dial, calculated for any given place, will also serve for any other place under the same meridian, provided its position in the latter place be parallel to its position in the former place. 2. The style of a dial is parallel to the axis of the earth; the meridian line is the intersection of the plane of the dial and the meridian of the place; the style is in the meridian, and inclines to the rational horizon in the same manner as the terrestrial axis, that is, by an angle equal to the latitude of the place. 3. The hour lines are the intersections of the face of the dial by 12 planes, inclined to each other by an angle of 15°, drawn from the meridian, and passing

through the style. If it is required to mark shorter intervals of time, as half hours, it is only necessary to conceive 24 planes, at an angle of 7½° with each other, and so on for any subdivisions. 4. The hour lines of a dial drawn on a plane are straight lines meeting in the centre of the dial, where the face is penetrated by the style. The forenoon and afternoon hour lines of the same number are given by the intersection of the same horary plane, on the opposite sides of the style. Sometimes the hour is indicated by means of a plate, placed before the dial, having a hole through which the light passes. It is only necessary that this hole should be one of the points of the style; the light will then fall upon that part of the dial where the shadow of the corresponding point of the style would be projected.

To render the theory of the dial still more intelligible, we give a diagram of an imaginary sphere, the degrees being indicated by the letters of the alphabet. P Q forms the imaginary axis, round which the sun is supposed to revolve. The slightest reference to this figure, and the accompanying article, will show how the shadows fall on the hour lines. Sun-dials are, however, in our climate, of comparatively small value. With a clear atmosphere, and an Italian sky, they would be more valuable than a common clock; but here a sun-dial, placed under the most favourable circumstances, would not supply the means for telling the hour for an average of one day in six.



DIAMETER; the straight line drawn through the centre of a circle, and touching the two opposite points of the circumference. It thus divides the circle into two equal parts, and is the greatest chord. The *radius* is half this diameter, and consequently the space comprehended between the centre and circumference of a circle.

DIAMOND; the hardest and most valuable of all the gems. Diamonds are of various colours; but the colourless, which is the sort mostly used in the arts, is when pure, perfectly clear, and pellucid as the purest water. Hence the phrases, the *water* of a diamond, a diamond of the finest *water*, &c. The colourless diamonds are not, however the most common. The rarest colours are blue, pink, and dark brown; but yellow diamonds, when the colour is clear and equal throughout, are very beautiful, and much valued. Pale blue diamonds are also very fine and rare, but deep blue still more rare. The largest diamond hitherto found is said to be in the possession of the Rajah of Mattan, in the island of Borneo, where it was found about eighty years since. It weighs three hundred and sixty-seven carats. It is described as having the shape of an egg, with an indentation near the smaller end. Many years ago, the Governor of of Batavia tried to purchase it, and offered in exchange one hundred and fifty thousand dollars, two large brigs of war, with their guns and ammunition, and other cannon, with powder and shot. But the rajah refused to part with a jewel, to which the Malays attach miraculous powers, and which they imagine to be connected with the fate of his family. This diamond is mentioned in the memoirs of the Batavian Society.

The diamond is the hardest of all known substances. Nothing will scratch it, nor can it be cut but by itself. By cutting, it acquires a brilliancy and play of lustre that much augment its price. The hardness of the diamond was well known to the ancients; its name, both in Greek and Latin implying invincible hardness. The ancients did not confine the word *adamas* to indicate the diamond alone, but applied it to other hard and *adamantine* substances. They were unacquainted with the art of cutting the diamond, satisfying themselves with those which were polished naturally: but knew of the property of its powder or dust for cutting, engraving, and polishing other stones. The art of cutting and polishing the diamond was unknown in Europe till the fifteenth century. Before that period, rough and unpolished ones were set as ornaments, and valued according to the beauty and perfection of their crystallization and transparency. This art is said to have been invented and first practised in 1456, by Louis de Berquen, a native of Bruges. Charles the Bold, Duke of Burgundy, was one of the first princes of modern times who affected a great splendour in diamonds. Among engraved or sculptured diamonds is one with a head, which Gori falsely imagined to be antique, and called it a portrait of Posidonius. It belongs to the Duke of Bedford. Lessing thinks that many of the engraved antique gems, which are called diamonds, are nothing but amethysts, sapphires, and emeralds, deprived of their colour by the operation of fire.

The number of known diamonds of 36 carats and upwards, are not more than nineteen, two only of which are in England, viz. the Piggott diamond weighing 45 carats, and worth 16,200*l.*; and one in the possession of the Hornsby family, of 36 carats, worth 8000*l.* Holland has but one, which weighs 53 carats, and is valued at 10,368*l.*; its form is conical, and it was for some time in the possession of Messrs. Rundell and Bridge, of London. France has two; the largest was bought by a former Duke of Orleans, during his regency, and thus called the Regency diamond; its weight is 136¼ carats, and value 149,058*l.* Germany has one weighing 139½ carats, and worth 155,682*l.* Russia is rich in these gems; its largest is that of the Sceptre, which is said to weigh 779 carats. If this be true, it must be worth, according to the general mode of estimating them, the enormous sum of 4,854,728*l.* The history of this diamond is rather curious; for a long time it formed the eye of an Indian idol, from which post it was removed by an European soldier; from him it passed through several hands, and was finally sold to the Empress Catherine, for 90,000*l.*, a handsome annuity, and a patent of

nobility. Russia has several others, one of which is estimated at 369,800*l*. The Great Mogul has one of a rose colour, and valued at 622,728*l*. The two principal ones belonging to Persia are called in the hyperbolical language of the east, "The Mountain of Splendour," &c., and "The Sea of Glory;" one is worth 145,800*l*. and the other 34,848*l*. The Portuguese royal family have two, one of which is still uncut; and, if we may credit the Portuguese accounts, is the largest ever found: it is said to weigh 1680 carats; and, supposing it to lose half its weight in cutting, it would be worth 5,644,800*l*., upwards of a million more than the Sceptre diamond of Russia. There is a small part broken off, which was done by the man who found it; who, ignorant what stone it was, struck it with a hammer upon an anvil. It was found at the Brazils. It may be proper to state, that some persons doubt the existence of this stone. According to the model exhibited, it is somewhat like the shape and size of an ostrich's egg. The other diamond, in the possession of the house of Braganza, is worth 3,698,000*l*.

An application of the diamond of great importance in the art of engraving, has been made within a few years by the late Wilson Lowry, for the purpose of drawing or ruling lines, which are afterwards to be deepened by aqua-fortis. Formerly steel points called *etching needles*, were used for that purpose; but they soon became blunt by the friction against the copper, so that it has always been found impracticable to make what are called *flat* or *even* tints with them; such as the azure of skies, large architectural subjects, and the sea in maps; but the diamond, being turned to a conical point, or otherwise cut to a proper form, is not worn away by the friction of the copper, and, consequently, the lines drawn by it are all of equal thickness. The diamond etching points of Mr. Lowry are turned in a lathe, by holding a thin splinter of diamond against them as a chisel.

Diamond, in *manufactures;* an instrument of considerable use in the glass manufactory, for squaring the large plates, or pieces; and among glaziers for cutting their glass. These diamonds are differently fitted up. That used for looking-glasses, and other large pieces, is set in an iron ferril two inches long, and a quarter of an inch in diameter. The rest of the cavity of the ferril is filled with melted lead, which keeps the diamond firm in its place. The glaziers have a handle of box or ebony, fitted into the ferril to hold it by.

Diapason. By the term *diapason*, the ancient Greeks expressed the interval of the octave. And certain musical instrument-makers have a kind of rule or scale, called the *diapason*, by which they determine the measures of the pipes, or other parts of their instruments. There is a diapason for trumpets and serpents. Bell-founders have also a diapason, for the regulation of the size, thickness, weight, &c., of their bells. *Diapason* is likewise the appellation given to certain stops in an organ. (See Stop.)

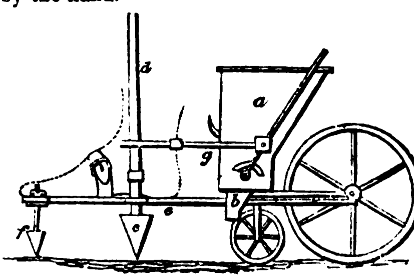
Diaper; so called from *Ypres* (*d'Ypres*); linen cloth woven in flowers and other figures; the finest species of figured linen after damask. Hence, as a verb, it signifies to diversify or variegate with flowers, or to imitate diaper.

Diaphragm, in *anatomy;* a large, robust, muscular membrane or skin, placed transversely in the trunk, and dividing the chest from the belly. In its natural situation, the diaphragm is convex on the upper side towards the breast, and concave on its lower side towards the belly; therefore, when its fibres swell and contract, it must become plain on each side: and consequently the cavity of the breast is enlarged, to give liberty to the lungs to receive air in inspiration; and the stomach and intestines are pressed for the distribution of their contents; hence the use of this muscle is very considerable. It is the principal agent in respiration, particularly in inspiration; for, when it is in action, the cavity of the chest is enlarged, particularly at the sides, where the lungs are chiefly situated; and, as the lungs must always be contiguous to the inside of the chest and upper side of the diaphragm, the air rushes into them, in order to fill up the increased space. In expiration, it is relaxed, and pushed up by the pressure of the abdominal muscles upon the viscera of the abdomen; and, at the same time that they press it upwards, they pull down the ribs, by which the cavity of the chest is diminished, and the air suddenly pushed out of the lungs.

Diatonic; a term in *music*, applied by the Greeks to that one of their three genera, which consisted, like the modern system of intervals, of major tones and semitones. The diatonic genus has long since been considered as more natural than either the chromatic or enharmonic. Aristoxenus asserts it to have been the first, and informs us that the other two were formed from the division of its intervals.

Diatonum Intensum, or Sharp Diatonic; the name given by musical theorists to those famous proportions of the intervals proposed by Ptolemy, in his system of that name; a system which, long after the time of this ancient speculative musician, was received in our counterpoint, and is pronounced by Doctor Wallis, Doctor Smith, and the most learned writers on harmonics, to be the best division of the scale.

Dibble; an agricultural implement employed in making holes in the ground for setting grains, plants, and other sorts of crops in, which are planted in rows. Their form, and the materials of which they are made, differs according to the nature of the crop which is to be put in or planted out by them; but for grain they are mostly shod with iron. In some cases they have likewise a sort of step for setting the foot upon, in using them. When employed, they are thrust into the ground to a depth suitable to the crop which is to be put in by them, and holes thus formed, into which the seeds, sets, or plants, are put by the hand.



We give the above engraving of a dibble acting by the foot as already described; *a* represents the depository for the seed, &c.; the discharge valve is shown at *b*, the opening and shutting of the hopper being by a double lever, *g*, resting against the heel above, *e*: the dibble-iron and guide is shown at *c f*.

Dice; cubical pieces of bone or ivory, marked with dots on each of their six faces, from one to six, according to the number of faces. Numerous passages in the ancient writers, and very many representations in marble or paintings, show how frequent dice-playing was among them. Different from the *tesseræ*, which were precisely like our dice, were the *tali* (which means, originally, the pastern bone of a beast). These were almost of a cubic form, and had numbers only on four sides, lengthwise. Three *tesseræ* and four *tali* were often used together; and the game with dice was properly called *alea*, though *alea* afterwards came to signify any game at hazard, and *aleator*, a gambler. Dice-playing, and all games of chance, were prohibited by several laws of the Romans, except in December, yet the laws were not strictly observed.

Diet. The dietetic part of medicine is an important branch, and seems to require a much greater share of attention than it commonly meets with. A great variety of diseases might be removed by the observance of a proper diet and regimen, without the assistance of medicine, were it not for the impatience of the sufferers. It may, however, on all occasions, come in as a proper assistant to the cure. That food is, in general, thought the best and most conducive to long life, which is most simple, pure, and free from irritating qualities, and is capable of being most easily converted into the substance of the body after it has been duly prepared by the art of cookery; but the nature, composition, virtues, and uses of particular aliments can never be learnt to satisfaction, without the assistance of practical chemistry. (See Food.)

Diet Drink; an alterative decoction employed daily in considerable quantities, at least from a pint to a quart. The decoction of sarsaparilla and mezereon, the Lisbon diet drink, is the most common and most useful.

Digester; an instrument invented by Mr. Papin. It consists of a strong vessel of copper or iron, with a cover adapted to screw on, with pieces of felt or pasteboard interposed. A valve with a small aperture is made in the cover, the stopper of which valve may be more or less loaded, either by actual weights, or by pressure from an apparatus on the principle of the steelyard. The purpose of this instrument is to prevent the loss of heat by evaporation. Water may be thus heated to 400° Fahr.; at which temperature its solvent power is greatly increased.

Digestion is that process in the animal body, by which the aliments are dissolved, and the nutritive parts separated, for the revivification of the frame. For the support and continuance of life in all classes of animals, we find a series of organs constructed by the all-wise Creator, for the purpose of preparing the food, so that its nutritious particles only shall be received into the circulatory system, and form a new portion of the vital fluid, in lieu of that which is constantly expended in the various secretions of the body, thus repairing the waste that is continually going on.

The organs that are employed for this purpose, are the stomach and intestines, liver, pancreas, or sweetbread, which may be severally described:—

The *stomach* is the well-known receptacle of the food, a large membranous bag, and is said to resemble in shape the Scotch bagpipes: it is situated immediately beneath the short ribs on the left side, and when distended with food or air, reaches nearly to the right. Like the intestines, it is composed of three coats; the external is denominated the serous, being formed of a reflection of the peritoneal lining of the abdominal cavity; the middle is formed of a tissue of muscular fibres, which perform an important office during digestion; the internal, from its resemblance to velvet, is named the villous; this is extremely vascular, and when minutely injected, either by blood or by artificial means, it resembles a mass of vermilion. To this coat the glands that secrete the gastric juice are connected, which, in some of the carnivorous birds, are extremely large, and whose ducts perforate this villous coat. Some anatomists assert the existence of a nervous coat to the stomach as well as to the intestines, but this has been denied; at the same time it must be admitted by every attentive anatomist, that it is abundantly supplied with nerves, which will account in many instances for those derangements of the constitution arising from indigestion. The left extremity is the greatest, and is denominated the larger curvature; the right is the lesser, and is attached to the first portion of the small intestines, by an intervening circular valve, denominated the pylorus. The stomach is supplied with blood by the first branch of the cœliac artery. The office of the stomach is to secrete a fluid for the purposes of digestion, and is denominated the gastric juice.

The small intestines are divided into three parts, viz. the *duodenum*, *jejunum*, and *ileum*; but this distinction may be considered arbitrary, inasmuch as there is no material difference in their structure. It consists of a long membranous tube, about an inch or an inch and a half in diameter, and is considered to be four times the length of the subject; notwithstanding this great length, it is collected by means of numerous windings and convolutions, into a comparatively small compass. These convolutions of the small intestine occupy the chief part of the umbilical region of the abdomen. They are connected in their situation by means of a broad folded membrane, called the *mesentery*. This production of the peritoneum is about six inches broad from its commencement, but it gradually expands, something after the manner of a fan, so that it becomes broad enough, ultimately, to cover the whole length of the small intestine. It keeps the different convolutions of the small intestines in their relative position, allowing at the same period, very considerable freedom of motion without the least danger of entanglement. If we trace the course of the small intestine, we follow the *duodenum* from the lesser extremity of the stomach in the right *hypochondrium*, which makes three turns close upon the spine, and then comes out just over the left kidney. The general direction of the canal from this point, independently of its various turnings and windings, is towards the right groin, where the *ileum* terminates by entering the *cæcum*.

The coats of the smaller intestines are similar in structure to the stomach, but as the villous coat in that organ is formed into a series of folds, so the analogy is continued to this portion of the alimentary canal, inasmuch as there are a great number of loose, transverse, and floating processes, named the *valvulæ conniventes*, by which means the extent of surface of the villous coat is considerably augmented. However, this peculiarity of structure is not found in the *fœtus*, and young subject, and is deficient in many

animals. Numerous glandular bodies are found in various parts of the canal, collected into small parcels, and hence they are called the *glandulæ aggregatæ*.

The large intestine is a canal of about two or three inches in diameter, and seven feet in length. It is divided into the cæcum, colon, and rectum. The cæcum is a kind of pouch situated in the right groin, and receiving the termination of the ileum. There is a valve placed at this part, by which means the contents of the intestine are allowed to pass from the ileum into the cæcum, but are prevented from returning. A small process, about the size of an earthworm is attached to the cæcum. It is consequently named the *appendix vermiformis cæci*, but its use is as yet unknown.

The course of the large intestine is as follows:—From the right groin it ascends on the same side of the abdomen over the kidney, under the name of colon: it turns completely over the abdomen at its upper part, immediately below the inferior margin of the stomach, and descends on the left side to the left groin: here it makes a large turn over the brim of the pelvis, and enters that cavity, where it takes the name of rectum, terminating in the anus.

The large intestines have the same number of coats of the small portions of this canal: but they have *no* valvulæ conniventes. The longitudinal muscular fibres are collected into three bands, which being shorter than the rest of the intestine, occasion the other coats to be gathered up in folds between them.

The next object of importance, as connected with digestion, is the liver, which is situated at the superior part of the abdomen; the use of this organ is to secrete the bile, a fluid intimately connected with chylification, a healthy supply of which is absolutely necessary for the nourishment of the animal. The bile is secreted from venous blood, collected from all the veins of the intestines and of the glands in the abdomen; and entering the liver by a large trunk, which is denominated the *vena portarum*, and is minutely distributed throughout its substance, in numerous and minute ramifications, and after an endless series of undefinable communications with each other, terminating in ducts so exceedingly minute as to exclude the red globules of the blood. This, in fact, is the commencement of the formation of the bile, which is carried on, the ducts gradually enlarging by an union of branches, till it is conveyed into one trunk, called the hepatic duct; this joining the cystic duct, forms the common bile duct, through which the bile is carried into the duodenum to assist in the process of chylification. As the circulation of this immense quantity of blood through the liver is constant and uniform, so is also the secretion of bile. But as this fluid is not always wanted in the duodenum, the great Author of Nature has provided it with a receptacle, called the gall bladder; to this organ the superabundant bile is conveyed by the cystic duct, where it remains until called for by the purposes of digestion. Human bile, according to M. Thenard, is composed, in 1,100 parts, of

Water	1000
A yellow insoluble matter, from . .	2 to 10
Albumen	42
Resin	41.
Soda	5.6
Phosphates of soda and lime, Sulphate and muriate of soda, and oxide of iron	45.

The *pancreas*, or sweet-bread, is a conglomerate gland, composed of minute portions united together by a cellular substance. It is connected by one end to the commencement of the duodenum, extending across the spine, behind the lesser arch of the stomach towards the spleen. Its length is about six inches, its breadth one and a half, and its thickness half an inch. It secretes a fluid necessary for chylification, called the pancreatic juice, but it is very small in quantity; and Dr. Majendie, of Paris, who has been making experiments on the pancreatic juice, observes, "*the quantity passed into the duodenum was scarcely a drop an hour*;" and, he says, "*I have waited longer than that for it*;" yet, small as it is in quantity, it performs a very important part in the elaboration of the chyle, as appears evident from the fact, that in diseases of the viscus, the body is attended with emaciation.

Having thus described the organs and fluids necessary for the process of digestion, we may now proceed to describe that process. The food is taken into the mouth, and broken down, or chewed by the teeth; it is then mixed with the saliva; it is next propelled by the muscles of the mouth into the pharynx, the constrictor muscles of which, propel it into the œsophagus or gullet; the contraction of its muscular parietes force it into the stomach, where it becomes mixed with the gastric juice; in a short time this juice acts on the food, and an homogenous mass is formed, called *chyme*, quite different from its original state. The pylrous dilates, the muscular coat of the stomach contracts, and the chyme is forced into the duodenum, where it mixes with the bile and pancreatic juice; the process of chylification then takes place, when the nutritious portions of the food are extracted by a series of vessels in the small intestines, called the lacteals, and from them it passes into a vessel lying on the spine, denominated the thoracic duct, which terminates in a large vein under the left collar bone, called the subclavian, where it enters the circulation of the blood. The useless and excrementitious parts pass through the large intestines, and are finally ejected.

Digestion, with chemists and apothecaries; the maceration of any substance which is to be softened or dissolved, commonly pulverized, in a solvent liquid. It is enclosed in a tight vessel, and exposed to a gentle heat for a longer or shorter time. By this process essences, elixirs, and tinctures are made.

DIGIT, in *arithmetic*, signifies any one of the ten numerals, 1, 2, 3, 4, 5, 6, 7, 8, 9, 0. The word comes from *digitus*, a finger; thus indicating the humble means originally employed in computations. Digit is also a measure equal to three-fourths of an inch.

Digit, in *astronomy*, is the measure by which we estimate the quantity of an eclipse. The diameter of the sun or moon's disc is conceived to be divided into 12 equal parts, called *digits;* and, according to the number of those parts or digits which are obscured, so many digits are said to be eclipsed. When the luminary is wholly covered, the digits eclipsed are precisely 12; and when it is more than covered, as is frequently the case in lunar eclipses, then more than 12 digits are said to be eclipsed.

DIGITALINE is the active principle of the *digitalis purpurea*, or foxglove, and is a very powerful poison, possessing all the properties of *digitalis*, in a very concentrated state. To prepare it, the leaves are di-

gested in ether, the solution filtered and evaporated, and the residue dissolved in water: this solution is heated with oxide of lead, filtered and evaporated, and the residuum digested in ether, which affords digitaline, on evaporation. It is a brown-coloured substance, deliquescent, and extremely bitter. It restores the colour of reddened litmus, and combines with acids.

Digitalis; a genus of plants, including, among other species, the purple foxglove, a vegetable which, as we have already stated, possesses important medicinal properties. The plant, when fresh, possesses a bitter, nauseous taste, and is violently emetic and cathartic. When prepared, and administered medicinally, it has the remarkable property of diminishing the strength and frequency of the pulse, and is, at the same time, diuretic.

Dike, or Dyke; a ditch or drain, and also a work of stone, timber, or fascines, raised to oppose the passage of the waters of the sea, a lake, river, or the like. In no country has the art of building dikes, and their subsequent management, been carried to so much perfection as in Holland, and the north-west of Germany, where the construction and superintendance of them, the draining of land and guarding against inundations, and the distribution of taxes for the maintenance of the dikes, form an important branch of government.

Dioptrics. See Optics.

Diorama. This term is now generally employed to describe pictorial representations. One of the principal of these is exhibited in the Regent's Park, and consists of two large transparent pictures, which are seen from a revolving room, so that the visitor can be brought alternately before either of the pictures. The effect of a thunder-storm, and, indeed, of variable lights generally, are in these pictures produced by differently coloured mediums through which the light is admitted, and these are made to move by machinery.

Diploe, in *anatomy*, is the reticular texture connecting together the two tables of the skull. (See Cranium.)

Dipping, among miners, signifies the interruption of a vein of ore—an accident that often gives them a great deal of trouble before they can discover the ore again.

Dipping Needle, or Inclinatory Needle; a magnetical needle, so hung, that instead of playing horizontally, and pointing north and south, one end dips or inclines to the horizon, and the other points to a certain height above it. The inventor of this instrument was Robert Norman, a compass-maker, of Wapping, about the year 1576.

Some persons have endeavoured to find the latitude and longitude of places by means of the dipping needle; but nothing of importance has followed from their attempts. The following general rule, however, may be adopted, in order to find the longitude or latitude by the dipping needle. If the lines of equal dip, below the horizon, be drawn on maps or sea-charts, from good observations, it will be easy from the longitude known, to find the latitude, and from the latitude known, to find the longitude. Suppose, for example, a person travelling or sailing along the meridian of London, and found the angle of dip, with a needle of one foot, to be 75°, the chart will show, that this meridian and the line of dip meet in the latitude of 53° 11′, which therefore is the latitude sought. Or suppose a person travelling along the parallel of London, *i. e.* in 51° 32′ N. lat., and he find the angle of dip to be 74°, this parallel, and the line of this dip, will meet in the map in 1° 46′ of E. lon. from London, which is therefore the longitude sought. The dip is not always the same.

Discord. A *discord* is a dissonant or inharmonious combination of sounds, so called in opposition to the *concord*, the effects of which the discord is calculated to relieve by contrast. Among various other discords, are those formed by the union of the fifth with the sixth, the fourth with the fifth, the seventh with the eighth, and the third with the ninth and seventh, all which require to be introduced by certain preparatives, and to be succeeded by concords to which they have some relation.

Discus, Disc, or Disk; among the Greeks and Romans, a quoit of stone or metal, convex on both its sides, perforated in the middle, and fastened to the hand by strings. Throwing the *discus* was one of the gymnastic exercises; and in the Olympic and other games, it was considered a great honour to conquer in the contest. Perseus is said to have invented this instrument, and Apollo killed his favourite, Hyacinth, with it. In some places, the plate which contains the host during the act of consecration, is called *disk*.

Diseases, Hereditary. The influence of the parents on the organization of the child is so great, that even the individual peculiarities which distinguish one man from another are, in part at least, transmitted to his children; hence the similarity, in person and looks, of the child to its parents. The internal organs, too, as well as the external form, have the same resemblance; so that the peculiar constitution, the greater or less activity and developement of these organs, are found to pass from parent to child. Now as it is the particular state of the several organs and functions, in which a very great part of diseases have their foundation, it follows that these diseases may be inherited; and, in fact, it has been observed, that the son is not unfrequently attacked by a disease at the same period of life in which his father was. These diseases are called *hereditary;* but it is only the predisposition to them that is, properly speaking, inherited. Hence the actual developement of hereditary diseases requires certain co-operating circumstances.

Constitutional diseases are very often not hereditary, but depend on circumstances which affect the fœtus, during pregnancy. The father has no influence on the child, beyond the act of generation; the mother operates upon it during pregnancy, and it is possible that hereby occasion may be given to hereditary diseases. Among the diseases which are most frequently hereditary, are scrofula, bleeding (especially at the lungs) and hemorrhoids, consumption, gout, the gravel and stone, scirrhus and cancer, disorders of the mind and spirits, hysterical and hypochondriac affections, apoplexy, epilepsy, and organic diseases of particular parts, especially of the heart. They have this peculiarity, that they are produced, and appear as constitutional diseases, more from the action of internal than of external, of predisposing than of occasional causes.

Such diseases are more difficult to reach and to cure than those which originate in accidental, external causes. Hence it is especially necessary to prevent in season their growth and developement. The means of doing this are the following: 1. Whoever has a hereditary predisposition to any disease, should

not marry one who has the same constitution. For this reason, marriages between near relations are not advisable, as tending to perpetuate such hereditary diseases. This too appears to be the reason why attachments are generally formed between persons of opposite constitution and different temperament. 2. We ought to order all the circumstances, in which the child grows up, in such a way, that the inherited predisposition may not only not be favoured, but counteracted. 3. The accidental occasions which favour the growth of the disease should be avoided, especially at the time of life in which the father was attacked by it. The medical treatment of hereditary diseases is not essentially different from that which is requisite in the same diseases, arising under different circumstances.

Disk, in *astronomy*, means the face of the sun and moon, as they appear to observers on the earth.

Dismounting, in the *military* art, is rendering the enemy's cannon unfit for further service, by breaking their carriages and axle-trees; also shattering the parapet of a retrenchment or of a wall, by balls, so that it cannot be defended, particularly so that cannons cannot be worked behind it. Dismounting batteries are such as are intended to throw down the parapets of fortifications, and disable the enemy's cannons. They are placed generally in the second, often in the third parallel. If they are on the glacis, in the salient angles of the bastions, and fire against the flanks of the adjacent bulwark, they are called *counter-batteries*. They are erected exactly opposite the front to be battered, and consist of from four to eight cannons, mostly 12-pounders. These cannons are generally aimed, at the same time, at the same embrasure, whilst the others occupy the other cannon of the enemy: when one of the enemy's cannon is silenced, the fire is directed to another, and so on. Some mortars and howitzers, which may be placed either within the dismounting battery or by themselves, support its fire, by bombarding the attacked embrasures: the fire of both must be slow, and well aimed. The distance of the dismounting battery from the work attacked, is usually from 3 to 400 paces, according to the distance of the second parallel. It has been proposed, in modern times, to shoot grenades, instead of balls, from the cannons, into the works which are to be dismounted, to produce an effect, by their bursting, similar to that of mines.

Dispensatory; a book in which all the medicines are registered, that are to be kept in an apothecary's shop, and the apothecaries directed how to compose them. Almost every country in Europe, and many large cities have their own dispensatories, which the apothecaries or chemists are bound to follow.

Displayed, in *heraldry*, is understood of the position of an eagle, or other bird, when it is erect, with its wings expanded, or spread forth.

Dissonance; that effect which results from the union of two sounds not in accord with each other. The ancients considered thirds and sixths as *dissonances*; and, in fact, every chord, except the perfect concord, is a dissonant chord. The old theories include an infinity of dissonances, but the present received system reduces them to a comparatively small number. One rule, admitted both by the ancients and the moderns, is, that of two notes, dissonant between themselves, the dissonance appertains to that one of the two which is most remote from the concord.

Distillation is an art founded upon the different tendencies which bodies have to pass into vapour, and to be condensed again by cold, and is performed in order to separate them from each other, when combined, or when they become products of chemical action. Its use is very important in obtaining spirits, essences, volatile oils, &c. The most common method of conducting this process consists in placing the liquid to be distilled in a vessel called a *still*, made of copper, having a moveable head, with a swan-like neck, which is so formed as to fit a coiled tube, packed away in a tub of water constantly kept cold, and which is termed a *refrigeratory*. The fire is applied either immediately to the still, or mediately, by means of a water or sand-bath. The liquid to be obtained rises, in vapour, into the head of the still, and, passing down the curved tube, or worm, becomes condensed, and makes its exit in a liquid state. The still should be constructed with a diameter considerably greater than its height, in order to expose a larger surface to the fire; and the tube should not be so narrow as to impede the passage of the vapour into the worm. (See Alcohol and Rectification.)

An improvement made by Mr. Tennant in this apparatus, consists in introducing the spiral tube into the body of a second still, so that the heat from the condensation of the steam passing through the tube, is applied to the distillation of liquor in the second. The pressure of the atmosphere is removed from the latter, by connecting it with an air-tight receiver, kept cool. The air in this receiver is allowed to escape at the commencement; its place is occupied by the steam from the liquor, which being condensed, a vacuum is kept up, and the distillation proceeds, without any farther heat being applied to the second still. This form of distilling apparatus is called the *double still*, and has been much improved by Mr. Sharp.

The process introduced by Mr. Barry, for preparing vegetable extracts and inspissated juices, by evaporation *in vacuo*, is of a somewhat similar nature. The apparatus consists of a hemispherical still, made of cast iron, and polished within. It is closed by an air-tight, flat cover, through which rises a wide tube, which is then bent downwards, and terminates in a large copper globe, of a capacity three or four times greater than that of the still.

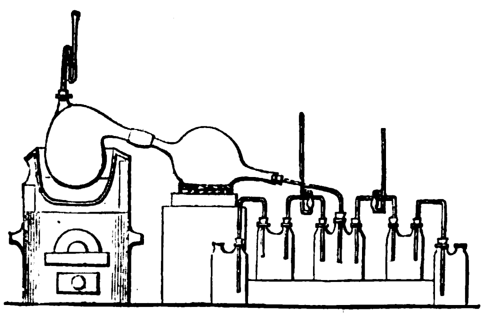
In this tube there is a stop-cock, between the still and the globe. When evaporation is to be performed, the vegetable juice or infusion is poured into the polished iron still, through an opening, which is then closed, made air-tight, and covered with water. In order to produce a vacuum, the connection between the still and copper receiver is interrupted, by shutting the stop-cock, and steam from a boiler is introduced by a pipe into the latter, till the whole of the air is expelled from it. This takes usually about five minutes, and is known by the steam issuing from the globe uncondensed. The copper sphere is then closed, and the communication restored between it and the still, by opening the stop-cock, when the greater part of the air in the latter rushes into the former. The stop-cock is again closed, and the globe again filled with steam as before. By the condensation of this steam, a vacuum is again produced, which, on opening the stop-cock, extracts the greater portion of the

air remaining in the still: in short, by repeating these exhaustions five or six times, an almost perfect vacuum is obtained, both in the still and receiver. Heat is then applied to the water-bath, in which the still is placed, until the juice within begins to boil, which is ascertained by inspection through a piece of thick glass, fixed firmly in the upper part of the apparatus.

As in a vacuum, fluids boil many degrees below their usual boiling temperature, water passes into ebullition, in such circumstances, at 90° Fahr., or a little above it; and it is never found necessary to heat the juice above a temparature of 100°. The evaporation is continued till the fluid is inspissated to the proper extent, which is judged by its appearance through the glass. Extracts prepared in this way, are found to be greatly preferable to those obtained by evaporation at a high temperature; they are considerably stronger, as the active principles in the juices are not decomposed by re-action between their elements, favoured by heat; and they are free from all burnt flavour, or empyreuma.

There are many operations, however, in which liquids are employed, that would corrode metallic vessels: in such cases, vessels are employed, constructed either of glass, platinum, or stone ware. In this case we generally employ a modification of Woulfe's bottles. This apparatus is one of the greatest improvements that could have been introduced in our laboratories. It not only affords us the means of collecting all the products of a distillation, but also enables us to obtain them separately; and it removes all fear of any risk or accident.

In certain cases, the product designed to be obtained by distillation, is an elastic fluid, not condensible by itself, but capable of being condensed by being transmitted through water, with which it is retained in combination. The distillatory apparatus invented by Woulfe, consists of a series of bottles, as shown in the accompanying diagram, connected with each



other by bent tubes, and connected with a retort, generally by the medium of a receiver and adopter. The receiver is designed to collect any condensible part of the product. In the three bottles, water is placed to nearly one half their height, and the tube passing from one into the other, beyond the second bottle, dips into the water of the bottle into which it is inserted. The gaseous product is thus transmitted through the water, by which, as well as by the pressure which is necessarily exerted by the short column of water in each tube, its absorbtion is promoted; and if any portion is incapable of being absorbed by the water, it passes off by the bent tube at the end, and may be collected in an inverted jar, in a trough of water. Each of the bottles, except the first receiver, has a straight tube, which rises to the height of 8, 10, or 12 inches above its insertion into the bottle, and passes so far within it as to dip in the water nearly half an inch. This tube is termed the tube of safety, and the use of it is to guard against that reflux of fluid which might happen from a partial vacuum arising from condensation in any of the bottles. At the commencement of the distillation, the joinings of the tubes with the bottles being well secured, the whole is air-tight; and, by the gas produced, the atmospheric air contained in the upper part of the bottles is in a great measure expelled through the tubes. If, therefore, in any stage of the distillation, the production of gas should diminish, the quantity contained in the bottles being absorbed by the liquor, a partial vacuum is formed; and, at the end of the process, when the retort cools, which always happens: the consequence of this must be, that the water being more pressed on by the atmospheric air without, than by the gas within, must pass backwards from one bottle to another by rising through the tubes, and thus the whole will be mingled together, which would often defeat the object of the distillation. This however, is effectually prevented by the tubes of safety, as when any such partial vacuum happens, the atmospheric air is forced through the small quantity of fluid in which they are immersed, and rising into the bottles, preserves the equilibrium.

Various improvements have been made in this apparatus. One defect in it is, that we cannot have the advantage of the immersion of the tube which comes from the first receiver, into the liquid in the second; for, as the receiver, as it sometimes is, is designed to collect the condensible product, and ought therefore, to be without water, it can have no tube of safety; and hence, if the tube issuing from it dip into the liquid in the second, whenever any condensation happens, from the gas ceasing to be produced, the liquor will pass backwards into it. As the liquid, however, in the first bottle is in the best situation for being impregnated with the gas, and therefore, for forming the most concentrated product, it is of some importance to aid this as much as possible, and obtain the advantage of the gas being forced to pass through it, by the tube passing into it being immersed. The contrivance that has been used for this purpose, is the tube of safety of Welter, or bent tube with an additional curvature, and a spherical ball intermediate between the globular receiver and the common three-necked bottle, and connecting them. In this is put a small quantity of water, so as to rise, when the pressure without and within is equal, about half way into the ball. If the elasticity is increased in the internal part of the apparatus, during the distillation, by the production of gas, the water is pressed upwards to the funnel at the top; if there is a condensation, it is forced by the atmospheric pressure, into the ball, but whenever it has passed the curvature beneath the ball, it is obvious that a portion of air must rise through it, and will pass into the globe or bottle, to the tube of which this bent tube is adapted.

Divergent, in *geometry*, are lines whose distance from each other are continually increasing.

Diverging Series, in analysis, are those series, the terms of which increase more and more, the farther they are continued.

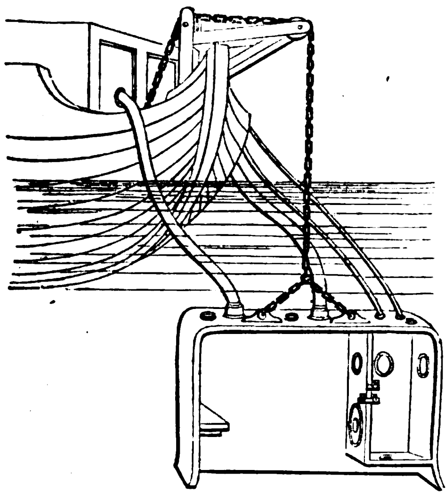
Diversion, in *military* affairs, is an attack on an

enemy, in a place where he is weak and unprovided, in order to draw off his forces from another place, where they have made, or intend to make, an irruption. Thus the Romans had no other way in their power of driving Hannibal out of Italy, but by making a diversion by attacking Carthage.

DIVIDED, in *arithmetic*, is that number to be divided.

DIVING-BELL. To illustrate the principle of this machine, let the experimentor take a glass tumbler, plunge it into water with the mouth perpendicularly downwards; he will find that very little water will rise into the tumbler, which will be evident if he lay a piece of cork upon the surface of the water, and put the tumbler over it; for it will be seen, that, though the cork should be carried far below the surface of the water, yet its upper side is not wetted, the air which was in the tumbler having prevented the entrance of the water; but, as air is compressible, it could not entirely exclude the water, which, by its pressure, condensed the air a little.

The general arrangement of the bell, as it is allowed to descend by its gravity in the water, will be understood by referring to the diagram beneath.



The first diving-bell we read of in Europe was tried at Cadiz, by two Greeks, in the presence of Charles V. and 10,000 spectators. It resembled a large kettle inverted. The first of any note was made by Dr. Halley. It is most commonly made in the form of a truncated cone, the smallest end being closed, and the larger one open. It is so suspended that it may sink full of air, with its open base downwards, and as near as may be parallel to the horizon, so as to close with the surface of the water. Mr. Smeaton's diving-bell, made in 1788, was a square chest of cast iron, 4½ feet in height, 4½ feet in length, and 3 feet wide, and afforded room for two men to work in it. It was supplied with fresh air by a forcing pump. This was used with great success at Ramsgate.

Other contrivances have been used for diving-bells. Within the last 30 years, the diving-bell has been much employed to assist in laying the foundations of buildings under water. A diving-bell, on an improved principle, was constructed in 1812, by the late Mr. Rennie, and employed in Ramsgate harbour, where it answered so well, that the masonry was laid with the utmost precision. From this period must be dated a new era in the construction of masonry under water, the use of coffer-dams being, in a considerable degree, superseded. The diving-bell was thenceforward employed by Mr. Rennie in the construction of all the great harbours which he projected. Round bells of cast-iron and copper have been occasionally made for the pearl and coral fisheries of South America, and have been supplied by the Messrs. Rennie for most of the royal dock-yards in England, and several of those in the colonies, for the pearl fishery at Ceylon, for the repair of the works at Cronstadt, and for many places in Great Britain and Ireland.

We shall now present our readers with a short description of a diving-bell, which was used at Sheerness in building a new sea-wall round the dock-yard at that place, and which is thought to be one of the best pieces of under-water masonry that has yet been constructed. This description is translated from the valuable work of M. Dupin, entitled, *Voyages dans la Grande-Bretagne*.

This particular bell is of cast-iron, of a single piece, and has the form of a hat without the rim. Its length at the base is 6 feet, its breadth 3 feet 9 inches, and its height 4 feet 6 inches. In the upper parts are several circular holes, in which glass illuminators are fixed, and made perfectly air-tight. By means of them, vision is sufficiently distinct at four fathoms below the surface of the water, to execute any kind of labour with precision. In the interior of the bell, there are two benches, on which the workmen sit down; some ring-bolts at the sides, to which the tools are fastened by means of cords, so that if the workmen let them fall, they cannot be lost;—and also ring-bolts at the top, with ropes for fastening the things to be brought up to the surface.

Between the two rows of illuminators, is a strengthening piece of iron, perforated with two large holes, in which is fixed the ends of the chain for lowering or raising the diving-bell. Exactly in the centre is a small round opening, in which is screwed a copper rim fixed to the end of a leather tube, for introducing fresh air into the bell when it is below the surface of the water.

Dr. Halley, the great improver of the diving-bell, used to supply his machine with fresh air, by sending down casks, which, by means of cords, could be conducted under the bell, and there opened above the surface of the water. This was found, however, to be a very inconvenient plan, and the bell at Sheerness is supplied with air by means of a forcing-pump and a leather tube. A raft is kept as near to the bell as possible, and on it a small air-pump is worked, which, by means of the leather tube already mentioned, continually renews the air in the bell. This pump is composed of a short cylinder of a large diameter, and of a piston moved by a lever. The piston has six circular openings, shut up in the body of the pump by leather valves set in copper, which open to permit the entrance of the air when the piston is raised, and which shut when it is depressed. In order to prevent the reflux of the air introduced into the bell, there is a valve at the end of the tube which closes when the piston is raised, and opens when it is forced down. By this mode of renewing the air, the workmen can remain under water for hours together without any inconvenience.

In employing this diving-bell to build under water, the first proceeding is, to drive two parallel rows of piles, one inside, the other outside, of the space where the intended wall is to be built. Beams are fastened on the tops of the piles, both from pile to pile, in the same row, and transversely from one pile to the opposite pile in the parallel row. On these transverse beams planks are laid, which form a strong floor, and on the edges two bars of iron with teeth are fixed, so as to form an iron railway or road, the whole length of the platform.

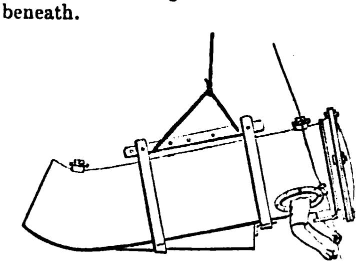
An uncovered waggon, the four wheels of which are teethed, so as to fit the teeth in these iron railways, is placed on them, and may be moved backwards and forwards along the line of the intended wall.

On the edges of this waggon, transversely with the line of the wall, other iron bars with teeth are fixed, with which the teeth in the four wheels of a second waggon correspond. The former waggon moves, therefore, along the line of the wall, while the latter moves on the former from side to side, or across the line of the wall. The tackle and ropes necessary for lowering or raising the bell, or the stones which are to be laid, are fixed to the second waggon. By the different movements of both the waggons, the bell can be carried to any and every point of the intended wall. Each of the waggons is moved by a double winch, on the axis of which are two pinion wheels, which work on two of the wheels of the waggons.

When it is intended to carry on the work, the stones ready prepared are suspended to the second waggon, and both are moved till each stone is over the place it is to occupy, and it is then lowered by a rope.

The people who descend under water in this machine, are said to feel at first a slight difficulty of breathing, attended with pain of the chest. On this, as well as on several other accounts, it is necessary to lower the bell very gradually and slowly. From being partly immersed in water, the workmen clothe themselves thickly and warmly; generally wearing the large boots, which scaffold men use. They also find it necessary to stuff their ears with cotton. On the whole, to descend frequently in the diving-bell, and to remain down long, is considered injurious to health; though the machine has not hitherto been sufficiently employed, to enable medical men to trace any particular disease which results from living under water.

It occasionally becomes necessary for the diver to proceed in a less cumbursome apparatus than the one we have now been describing. Such a machine is represented beneath.



It is supported by a chain or rope, and the diver is provided with a small cord shown in the engraving, by which his signals are made to the persons who have charge of the machine. An air-pump and pipe must be employed in this as well as in the former arrangement.

The large diving-bell has lately been used with great advantage in raising treasure from his Majesty's ship, Thetis, which was accomplished in a very tempestuous part of the ocean.

Divining Rod, is a rod made with certain superstitious ceremonies, either single and curved, or with two branches like a fork, of wood, brass, or other metal. The rod is held in a particular way, and if it bends towards one side, those who use the rod believe it to be an indication that there is treasure under the spot. Some publications respecting a man who, in quite recent times, pretended to be able to discover water and metals under the ground by his feelings, attracted much attention.

Divisibility. The actual subdivision of bodies has, in many cases, been carried to a prodigious extent. A slip of ivory, of an inch in length, is frequently divided into a hundred equal parts, which are distinctly visible. But, by the application of a very fine screw, 5000 equidistant lines, in the space of a quarter of an inch, can be traced on a surface of steel or glass with the fine point of a diamond, producing delicate iridescent colours. Common writing paper has a thickness of about the 500th part of an inch; but the pellicle separated from ox-gut, and then doubled to form gold-beaters' skin, is six times thinner.

A single pound of cotton has been spun into a thread 76 miles in length; and the same quantity of wool has been extended into a thread of 95 miles; the diameters of those threads being hence only the 350th and 400th part of an inch.

But the ductility of some metals far exceeds that of any other substance. The gold-beaters begin with a riband an inch broad and 150 inches long, which has been reduced, by passing through rollers, to about the 800th part of an inch in thickness. This riband is cut into squares, which are disposed between leaves of vellum, and beat by a heavy hammer, till they acquire a breadth of more than three inches, and are therefore extended ten times. These are again quartered, and placed between the folds of gold-beaters' skin, and stretched out, by the operation of a lighter hammer, to the breadth of five inches. The same process is repeated, sometimes more than once, by a succession of lighter hammers; so that 376 grains of gold are thus finally extended into 2000 leaves of 3.3 inches square, making in all 80 books, containing each 25 leaves. The metal is, consequently, reduced to the thinness of the 282,000th part of an inch, and every leaf weighs rather less than the 5th part of a grain. Silver is likewise capable of being laminated, but will scarcely bear an extension above half that of gold, or the 150,000th part of an inch thick. Copper and tin have still inferior degrees of ductility, and cannot, perhaps, be beat thinner than the 20,000th part of an inch. These form what is called *Dutch leaf*.

In the gilding of buttons, five grains of gold, which is applied as an amalgam with mercury, is allowed to each gross; so that the coating left must amount to the 110,000th part of an inch in thickness. If a piece of ivory or white satin be immersed in a nitro-muriate solution of gold, and then plunged into a jar of hydrogen gas, it will become covered with a surface of gold hardly exceeding in thickness the 10,000,000th part of an inch. The gilt wire used in embroidery is formed by extending gold over a surface of silver.

A silver rod, about two feet long, and an inch and a half in diameter, and weighing nearly 20 pounds, is richly coated with about 800 grains of pure gold. In England, the lowest proportion allowed is 100 grains of gold to a pound of silver. This gilt rod is then drawn through a series of diminishing holes, till it has stretched to the vast length of 240 miles, when the gold has, consequently, become attenuated 800 times, each grain covering a surface of 9600 square inches. This wire being now flatted, the golden film suffers a farther extension, and has its thickness reduced to the four or five millionth part of an inch. It has been asserted, that wires of pure gold can be drawn of only the 4000th part of an inch in diameter. But the late Dr. Wollaston, by an ingenious process, advanced much farther. Taking a short cylinder of silver, about the third part of an inch in diameter, he drilled a fine hole through its axis, and inserted a wire of platinum, only the 100th part of an inch thick. This silver mould was now drawn through the successive holes of a steel plate, till its diameter was brought to near the 1500th part of an inch, and, consequently, the internal wire being diminished in the same proportion, was reduced to between the four and five thousandth part of an inch. The compound wire was then dipped in warm nitric acid, which dissolved the silver, and left its core, or the wire of platinum. By passing the incrusted platinum through a greater number of holes, wires still finer were obtained, some of them only the 30,000th part of an inch in diameter. The tenacity of the metal, before reaching that limit, was considerable; a platinum wire of the 18,000th part of an inch in diameter, supporting the weight of one grain and a third. Such excessive fineness is hardly surpassed by the filamentous productions of nature. Human hair varies in thickness, from the 250th to the 600th part of an inch. The fibre ot the coarsest wool is about the 500th part of an inch in diameter, and that of the finest only the 1500th part.

The silk line, as spun by the worm, is about the 500th part of an inch thick; but a spider's line is, perhaps, six times finer, or only the 30,000th part of an inch in diameter; insomuch, that a single pound of this attenuated substance might be sufficient to encompass our globe. The red globules of the human blood have an irregular, roundish shape, from the 2500th to the 3300th of an inch in diameter, with a dark central spot. The trituration and levigation of powders, and the accidental abrasion and waste of the surface of solid bodies, occasion a disintegration of particles, almost exceeding the powers of computation.

Emery, after it has been ground, is thrown into a vat filled with water, and the fineness of the powder is distinguished by the time of its subsidence. In very dry situations, the dust lodged near the corners and crevices of ancient buildings is, by the continual agitation of the air, made to give a glossy polish to the interior side of the pillars and the less prominent parts of those venerable remains. So fine is the sand on the plains of Arabia, that it is carried sometimes 300 miles over the Mediterranean, by the sweeping sirocco. Along the shores of that sea, the rocks are covered by the pholas, a testaceous and edible worm, which, though very soft, yet, by unwearied perseverance, works a cylindrical hole into the heart of the hardest stone. The marble steps of the great churches in Italy are worn by the incessant crawling of abject devotees; nay, the hands and feet of bronze statues are, in the lapse of ages, wasted away by the ardent kisses of innumerable pilgrims that resort to those shrines. What an evanescent pellicle of the metal must be abraded at each successive contact! The solutions of certain saline bodies, and of other coloured substances, exhibit a prodigious subdivision and dissemination of matter.

A single grain of the sulphate of copper, or blue vitriol, will communicate a fine azure tint to five gallons of water. In this case, the copper must be attenuated at least ten million times; yet each drop of the liquid may contain as many coloured particles, distinguishable by our unassisted vision. A still minuter portion of cochineal, dissolved in deliquiate potash, will strike a bright purple colour through an equal mass of water. Odours are capable of a much wider diffusion. A single grain of musk has been known to perfume a large room for the space of 20 years. Consider how often, during that time, the air of the apartment must have been renewed, and have become charged with fresh odour! At the lowest computation, the musk had been subdivided into 320 quadrillions of particles, each of them capable of affecting the olfactory organs.

The vast diffusion of odorous effluvia may be conceived from the fact, that a lump of assafœtida, exposed to the open air, lost only a grain in seven weeks. Yet, since dogs hunt by the scent alone, the effluvia emitted from the several species of animals, and from different individuals of the same race, must be essentially distinct. The vapour of pestilence conveys its poison in a still more subtile and attenuated form. The seeds of contagion are known to lurk, for years, in various absorbent substances, which scatter death on exposure to the air. But the diffusion of the particles of light defies all powers of calculation.

A small taper will illuminate the atmosphere to the distance of four miles; yet the luminous particles, which fill that wide concavity, cannot amount to the 5000th part of a grain, which may be the whole consumption of the wax in light, smoke, and ashes. Animated matter likewise exhibits, in many instances, a wonderful subdivision. The milt of a codfish, when it begins to putrify, has been computed to contain a billion of perfect insects; so that thousands of these living creatures could be lifted on the point of a needle. But the infusory animalcules display, in their structure and functions, the most transcendant attenuation of matter. The *vibrio undula*, found in duck-weed, is computed to be ten thousand million times smaller than a hemp seed. The *vibrio lineola* occurs in vegetable infusions, every drop containing myriads of those oblong points. Of the *monas gelatinosa*, discovered in ditch water, millions appear in the field of a microscope, playing, like the sunbeams, in a single drop of liquid. Insects have been discovered so small as not to exceed the 10,000th part of an inch, so that 1,000,000,000,000 of them might be contained within the space of one cubic inch; yet each animalcule must consist of parts connected with each other, with vessels, with fluids, and with organs necessary for its motions, for its increase, for its propagation, &c. How inconceivably small must those organs be! and yet they are, unquestionably, composed of other parts still smaller, and still farther removed from the perception of our senses.

Division. At the conclusion of the article **Algebra** we referred to this head for one or two examples of a peculiar character. The first we shall give is of frequent application; it is the division of a^m-b^m by $a-b$ without remainder, and is remarkable for the mode of reasoning necessary to effect it.

We have already seen that the product of $a+b$ by $a-b$ is a^2-b^2; consequently a^2-b^2 divided by $a-b$ gives $a+b$ as quotient. Similarly we find that a^3-b^3 divided by $a-b$ gives the quotient a^2+ab+b^2; and that a^4-b^4 divided by $a-b$ gives that of $a^3+a^2b+ab^2+b^3$. Speaking generally, then, a^2-b^2, a^3-b^3, and a^4-b^4 are each severally divisible without remainder by $a-b$. This we ascertain to be a fact by actually performing the division; and if we were to make the trial, we should also find that a^5-b^5, a^6-b^6, a^7-b^7 were each divisible exactly by $a-b$. Reasoning then from analogy, we might conclude that whatever was the exponent of the two letters a and b, their difference would always be divisible by $a-b$ without remainder. But analogy is not sufficient to authorise the assertion of such a fact; we must have proof, and this may be obtained in the following manner:

Let us call the exponent m, and try to divide a^m-b^m by $a-b$.

We have then, according to the rules of division,

$$\begin{array}{rl} a^m-b^m & \big\rangle\ a-b. \\ \text{1st. Remainder: . . . . . } +a^{m-1}b-b^m & \big\rangle\ a^{m-1}. \end{array}$$

Dividing a^m by a, we obtain a^{m-1} for the first term of the quotient, and have a remainder $a^{m-1}b-b^m$, which may be put under the form of $a^{m-1}\times b-b^{m-1}\times b$, or $b\,(a^{m-1}-b^{m-1})$. Now the exact divisibility of a^m-b^m by $a-b$, depends of course upon whether this remainder is divisible exactly by $a-b$; in other words, if $b(a^{m-1}-b^{m-1})$ be so divisible, then a^m-b^m is. But if we examine the remainder, we shall perceive that it is merely b multiplied by the difference of a and b, each of these two letters being raised to a power one degree lower than in the original dividend a^m-b^m. If, then, $a^{m-1}-b^{m-1}$ be exactly divisible by $a-b$, a^m-b^m is so also. In other words, if the difference of two numbers, each of which is raised to a *certain power*, be exactly divisible by the difference of those numbers, then their difference, when each is raised to a *power of one degree greater* is also divisible by that difference without remainder. But a^2-b^2 is exactly divisible by $a-b$; and the operation gives the quotient $a+b$. Consequently a^3-b^3 is so divisible also; the quotient being $a^2+b\left(\dfrac{a^2-b^2}{a-b}\right)$ or $a^2+b(a+b$ or a^2+ab+b^2. Similarly $\left(\dfrac{a^4-b^4}{a-b}\right)$ gives without remainder the quotient $a^3+b\left(\dfrac{a^3-b^3}{a-b}\right)$, or $a^3+b\,(a^2+ab+b^2)$, or $a^3+a^2b+ab^2+b^3$; and generally $\dfrac{a^m-b}{a-b}$ gives without remainder the whole quotient $a^{m-1}+a^{m-2}b+a^{m-3}b^2 \ldots\ldots\ldots +ab^{m-2}+b^{\;-1}$.

The method of reasoning just adopted in the proof of the proposition of the divisibility without remainder of a^m-b^m by $a-b$ is of very frequent occurrence in algebra, and should be well comprehended by the student. It is a species of induction, and forms one of the most powerful engines of demonstration which the mathematician possesses.

Let it be proposed to divide 1 by $1+x$.

$$\begin{array}{l|l} 1 & 1+x \\ \underline{1+x} & \overline{1-x+x^2-x^3+,\ \text{\&c.}} \\ -x & \\ \underline{-x-x^2} & \\ \quad x^2 & \\ \quad \underline{x^2+x^3} & \\ \quad -x^3 & \end{array}$$

The division it is evident will never end, and we have then

$$\frac{1}{1+x}=1-x+x^2-x^3+x^4-,\ \text{\&c.}$$

Now, as x stands for no particular number, the above result is true, when it is replaced by any, whatsoever. Put 1 for it, and we have

$$\frac{1}{2}=1-1+1-1+1-1+1,\ \text{\&c.}$$

This result was a source of embarrassment to some mathematicians who, thinking that the &c. must comprise a set of terms exactly the same as those that go before it, could not understand how a series of numbers which when added together is alternately 0 or 1, can ever be equal to $\frac{1}{2}$. If the remainder however be taken into account, the result is perfectly intelligible; for that remainder is always some power of x, and, divided by $1+x$, it becomes in the case of $x=1$, $\frac{1}{1+1}$, or $\frac{1}{2}$; and we have

$$\frac{1}{2}=1-1+1-1+1-1+\frac{1}{2};$$

or,

$$\frac{1}{2}=1-1+1-1+1-1+1-\frac{1}{2}$$

both of which are perfectly correct.

The following examples will be useful exercises; observing that $2n$ is merely intended as the general representative of every exponent which is an even number; for n may be either even or odd, but $2n$ (always premising that n is whole) must of necessity be even, or capable of being divided by 2 and leaving a whole number for quotient; and $2n+1$ must be odd. The possibility of performing the following divisions without having any remainder left, and the certainty of obtaining the quotients marked down, is to be proved.

$$\frac{an-1}{a-1}=a^{n-1}+a^{n-2}+\ldots\ldots\ldots+a+1$$

$$\frac{a^{2n+1}+1}{a+1}=a^{2n}-a^{2n-1}+\ldots\ldots\ldots+a^2-a+1$$

$$\frac{a2n-1}{a+1}=a^{2n-1}-a^{2n-2}+\ldots\ldots\ldots-a2+a-1$$

Docks. The word *dock* was formerly applied to the slip or excavation made for the purpose of building or repairing a vessel; and was distinguished as a *dry dock* when furnished with flood-gates to prevent the influx of the tide, if required; and as a *wet dock* when, having no flood-gates, the vessel could only be cleaned or repaired during the period in which the tide left her accessible. These slips or docks are still used. At present, the name of *graving*

or *building dock* is more generally given to what we have termed *dry dock*, which latter term is applied to those docks or basins left dry by the tide; while the appellation of *slip* is confined to the narrow inlet for building or repairing, unprotected by gates.

During the growth of the maritime power and the commerce of Europe, it was found highly inconvenient to load and unload vessels in a tide-river or in a harbour not entirely land-locked; for either the ships could not be brought close to the wharfs, or, when conducted there at the flood of the tide, they were left dry at the ebb, and suffered considerable damage by straining, by delay from neap tides, and other accidents and inconveniences. To obviate these inconveniences, improvements in the existing docks or slips were made from time to time, until England, taking the lead, introduced a system of floating docks, which have greatly contributed to her advancement and prosperity.

Many of the principal maritime ports of Europe are provided with dry docks for building and repairing vessels; and of these, Toulon, Havre, and Brest, have the most remarkable. Most seaport towns are provided with graving docks for the repairing of ships; but it is only in the British islands that the system has been carried to any extent of forming large basins or floating docks, furnished with floodgates for the reception of shipping to load and unload, wherein the vessel remains safe at the quay-side. The docks of Liverpool were the first constructed in England; and many other maritime powers have been induced to follow her example. It is scarcely fifty years since nearly the whole of the vessels that entered the port of London were obliged to remain moored in the open stream of the Thames.

The example which Liverpool had set for nearly a century, pointed out the remedy for the existing evils, and the constructing of floating docks in the port of London was resolved on. The first constructed, and those nearest the trading part of the metropolis, are called the *London Docks*. They are below the site of the Tower, and on the left bank of the Thames; were begun in 1800, and completed in 1805. The dock, properly so called, is 420 yards in length, 276 yards in breadth, and 29 feet in depth; its superficies are equal to 25 acres; that of the basin communicating with it is above 2½ acres; and, including the ground occupied by warehouses, sheds, and quays, the whole premises contain a superficies of 110 acres. Excepting those ships that trade to the East and West Indies, every vessel, whether English or foreign, may enter the London Dock upon paying the duties, to unship her cargo, or take in a new lading.

For the convenience of business, ranges of sheds, low, and of a very simple construction, have been erected along the sides of the dock, and near the edges of the quays, into which cargoes are removed. Behind these sheds, and in a parallel direction to them, stands a line of magnificent warehouses, four stories high, with spacious vaults, into which the casks are conveyed by inclined planes. These buildings occupy a superficies of 120,000 square yards. The cellars are appropriated to wines and brandies, and railways, or rather tramways, running in all directions, facilitate labour. The London Docks have their several parts perfectly adapted to each other, and are of the most admirable construction. The gates, like all those whose size much exceeds 20 feet, instead of being straight, are curved on the side on which the water presses.

The *West India Docks* are on the left bank of the Thames, at the distance of about one mile and a half below the London Docks. They are situated on the base of a tongue of land of the Isle of Dogs—a sort of peninsula formed by a long circuit of the river. The West India Docks are much superior to the London, both in extent and regularity. These vast works were undertaken and executed by an association of private individuals, and by means of a mere subscription. Twenty-seven months sufficed to accomplish the whole. The excavations of the West India Docks were begun on the 12th of July, 1800; and as early as the month of September, 1802, vessels entered the import dock! At the highest tides, the depth of water in the two docks is 24 feet; they are formed parallel to each other; their common length is about 890 yards. The largest, which has a superficies of about 30 acres, is destined for those vessels returning to the West Indies, which deposit their cargoes in the warehouses of this artificial port. The second, the superficies of which is about 25 acres, receives the vessels laid up in ordinary, or taking the outward-bound cargoes.

These docks, with their basins, and the locks which connect them with the river, present an area of 68 acres of ground, excavated by human hands, for the reception and moorage of vessels. The total superficies, including that of the quays and warehouses, is 140 acres. During the busy season, this establishment employs about 3000 workmen. It can admit, at the same time, 204 vessels in the import, and 195 in the export dock, forming a total of 120,000 tons. During the first 15 years, 7260 vessels entered them. Upon the quays, under the sheds, and in the warehouses, there have been deposited, at the same time, 148,563 barrels or casks of sugar, 70,875 barrels, and 433,648 bags of coffee, 35,158 pipes of rum and Madeira wine, 14,021 logs of mahogany, 21,350 tons of logwood, &c. At the upper and lower entrances of the two docks, a basin presents three locks of communication. The first communicates with the Thames; the water is kept in it by means of double gates. The second and third locks lead respectively into the export and import docks; they have also double gates. By this means, the vessels are able to come in and go out independently of the state of the tide; they may remain in the basin as long as is judged convenient. The water of the docks being but very little higher than that of the basins, it does not press violently on the gates of the locks. It should be also observed, that this water having had time to settle in its previous passage through the basin, hardly deposits any sediment when introduced into the docks. The *East India Docks*, belonging to the East India Company, are inferior to the West India Docks in magnitude, but equal in point of construction and security of property. Having to receive vessels of 2500 tons, they are deeper than the West India Docks, and have never less than 23 or 24 feet water.

The docks erected on the site of St. Katherine's Church, near the Tower of London, are also works of great magnitude; though they do not materially differ from those already described.

DOG-BANE contains a bitter extractive principle, soluble in water and alcohol, a colouring principle soluble in water only, a very large quantity of caout-

chouc, and a volatile oil.—It is a very active plant, highly valued by the American Indians. The root is the most powerful part, and is much employed by the physicians of that country instead of ipecacuanha. Thirty grains of the recently powdered root evacuate the stomach as effectually as two-thirds of this quantity of ipecacuanha, by which name it is known in various parts of the Eastern States of America. Its power is diminished by keeping, and destroyed by age. It is given in small doses as a tonic medicine.

DOG-DAYS. This name is applied to the period between the 24th July and 24th August, because the dog-star (Sirius), during this period, rises with the sun. The heat, which is usually most oppressive at this season, was formerly ascribed to the conjunction of this star with the sun.

DOGGER; a Dutch vessel navigated in the German Ocean; it is equipped with two masts, a main and a mizzen-mast, and somewhat resembles a ketch. It is principally used for fishing on the Dogger Bank.

DOG-GRASS. This root is much used in medicine. Among the demulcent substances, dog-grass is one of the most frequently employed in France. It is used in most of the inflammatory and febrile diseases, and especially in those of the urinary passages. It was formerly recommended as a powerful diuretic, and was employed as such in dropsies: but we know, at present, this opinion to be erroneous.

DOG-STAR; Sirius; the star that gives their name to the dog-days.

DOG-WOOD. The bark of this tree, as well as that of several other species of cornus inhabiting Canada and the Northern States, possesses similar properties with the Peruvian bark, and is employed successfully in the cure of intermittent fevers. The bark of the root, stem, and branches tastes very much like this famous bark; it is bitter, astringent, and slightly aromatic. Its astringency is, however, stronger than that of Peruvian bark. This bark is, without doubt, one of the most valuable native medicines. As a substitute for the Peruvian bark, much has been written in commendation of it. The resemblance extends to its chemical and physical, as well as therapeutical properties. The bark of the dog-wood is extensively employed by American practitioners in intermittent fevers, and the report they give of it is very favourable and satisfactory. It is remarked that, in its recent state, it is apt to disagree with the stomach, and to produce pains in the bowels; but, in order to prevent this effect, it is simply needful to add to it, when used, a few drops of laudanum, or to use the bark after it has been collected for some time. This bark may be used with still greater advantage in intermittents, if combined with serpentaria.

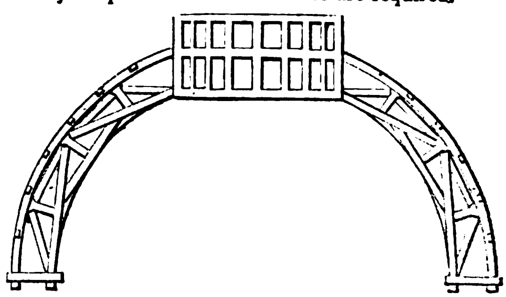
DOIT was the ancient Scottish penny-piece, of which twelve were equal to a penny sterling. Two of them were equal to the bodle, six to the baubee, and eight to the acheson. There was also in Lower Germany a small coin called *deut* (pronounced like *doit*) and *dütchen*, the diminutive of *deut*. In the Netherlands, the coin is called *dayt*, and Frisch believes that these words took their origin from the French *tête*, head; the piece of 20 kreuzer is still called, in Germany, *kopstück* (head-piece).

DOLLAR; a coin differing in its value. This word corresponds to the German *thaler*, the Low-German *dahler*, the Danish *daler*, the Italian *tallero*. All these words, together with our *dollar*, are derived from the name of the Bohemian town *Joachims-Thal* (Joachim's Valley), where in 1518, the Count of Schlick coined silver pieces of an ounce weight. These, indeed, were not the first of the kind coined; yet, as they were numerous and very good, they became generally known by the name of *Joachimsthaler*, which is the German adjective of *Joachimsthal*, and also *Schlickenthaler*, from the name of the counts. As these coins were in good repute, *thalers* were also coined in other countries, but of different value: thus originated the *laub-thaler* (leaf-dollar) *Philipps-thaler*, the Swedish copper dollar, &c. In Russia, a dollar is called *jephimock*, from *Joachim*.

DOLOMITE, in *mineralogy*. See NATURAL HISTORY Division.

DOME, in *architecture*. Some of the greatest engineers both in this country and Italy, have given their particular attention to this branch of building. Michael Angelo and Sir Christopher Wren have executed the finest in Europe.

The frame-work intended to support a simple dome, in which neither masonry or brick-work are employed, is shown beneath; but that arrangement is only adopted when small domes are required.

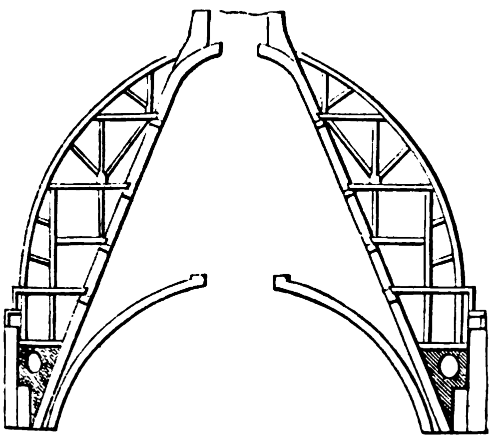


The construction of a dome is less difficult than that of an arch, since the tendency of each part to fall is counteracted, not only by the pressure of the parts above and below, but also by the resistance of those which are situated on each side. A dome may therefore be erected without any temporary support, like the centre which is required for the construction of an arch; and it may at last be left open at the summit, without standing in need of a keystone, since the pressure of the lower parts is sufficiently resisted by the collateral parts of the same horizontal tier, to prevent the possibility of their falling in, or of their forcing out the upper parts. The weight of the dome may, however, force out its lower parts, if it rises in a direction too nearly vertical; and supposing its form spherical, and its thickness equal, it will require to be confined by a hoop or chain as soon as the span becomes eleven-fourteenths of the whole diameter. But if the thickness of the dome be diminished as it rises, it will not require to be bound so high: thus, if the increase of thickness in descending begin at about thirty degrees from the summit, and be continued until at about sixty degrees, the dome becomes little more than twice as thick as at first, the equilibrium will be so far secure; and at this distance it would be proper to employ either a chain, or some external pressure, to prove the stability, since the weight itself would require to be increased without limit, if it were the only source of pressure on the lower parts.

The dome of the Pantheon at Rome is nearly circular, and its lower parts are so much thicker than

its upper parts, as to afford a sufficient resistance to their pressure: they are supported by walls of great thickness, and furnished with many projections which answer the purpose of abutments and buttresses.

The dome of St. Paul's is justly considered as a master-piece of architectural skill; but even with all its excellence and scientific arrangement, Sir Christopher Wren found it necessary to bind in the masonry by a vast connected link of iron. The interior cone of brick-work on which depends the internal frame-work is shown in the section.



Dominical Letter, in the calculation of time, properly called *Sunday letter;* one of the seven letters of the alphabet, A B C D E F G, used in almanacs, ephemerides, &c., to designate the Sundays throughout the year. In our almanacs, the first seven letters of the alphabet are commonly placed to show on what days of the week, the days of the month, fall throughout the year. And because one of those seven letters must necessarily stand against Sunday, it is printed in a capital form, and called the *dominical letter;* the other six being inserted in different characters, to denote the other six days of the week. Now, since a common Julian year contains 365 days, if this number be divided by 7 (the number of days in a week), there will remain one day. If there had been no remainder, it is obvious the year would constantly begin on the same day of the week; but, since one remains, it is plain that the year must begin and end on the same day of the week; and therefore the next year will begin on the day following. Hence, when January begins on Sunday, A is the dominical or Sunday letter for that year: then, because the next year begins on Monday, the Sunday will fall on the seventh day, to which is annexed the seventh letter, G, which, therefore, will be the dominical letter for all that year: and as the third year will begin on Tuesday, the Sunday will fall on the sixth day; therefore F will be the Sunday letter for that year. Whence it is evident, that the Sunday letters will go annually in retrograde order, thus, G, F, E, D, C, B, A; and in the course of seven years, if they were all common ones, the same days of the week and dominical letters would return to the same days of the months. But, because there are 366 days in a leap-year, if the number be divided by 7, there will remain two days over and above the 52 weeks, of which the year consists. And, therefore, if the leap-year begins on Sunday, it will end on Monday; and as the year will begin on Tuesday, the first Sunday thereof must fall on the 6th of January, to which is annexed the letter F, and not G, as in common years.

By this means, the leap-year returning every fourth year, the order of the dominical letters is interrupted, and the series cannot return to its first state till after four times seven, or 28 years; and then the same days of the months return in order, to the same days of the week as before.

The dominical letter may be found universally, for any year of any century, thus: Divide the centuries by 4, and take twice what remains from 6; then add the remainder to the odd years, above the even centuries, and their 4th. Divide their sum by 7, and the remainder taken from 7, will leave the number answering to the letter required. Thus, for the year 1878, the letter is F. For the centuries, 18, divided by 4, leave 2; the double of which, taken from 6, leaves 2 again; to which add the odd years, 78, and their 4th part, 19, the sum, 99, divided by 7, leaves 1, which, taken from 7, leaves 6, answering to F, the sixth letter in the alphabet.

Donjon, in *fortification,* signifies a strong tower or redoubt, into which the garrison of an ancient fortress could retreat in case of necessity. The donjon keep was more common in Scottish than in English fortresses.

Dormant state of animals. We are all accustomed to see a large part of creation, during summer, in great activity, and in winter returning to an apparently inanimate state: we mean the plants; but this phenomenon is not common in the case of animals. There is, however, a small number of animals, which, besides the daily rest that they have in common with most other animals, remain, during some months in the year, in an apparently lifeless state; at least, in utter inactivity. Except the hedgehog and the bat, all the *mammalia* subject to this dormant state, belong to the class of digitated animals. They are found not only in cold climates, but in very warm ones; for instance, the jerboa, in Arabia, and the taurick, in Madagascar. The period of long sleep generally begins when the food of the animal begins to become scarce, and inactivity spreads over the vegetable kingdom. Instinct, at this time, impels the animals to seek a safe place for their period of rest. The bat hides itself in dark caves, or in walls of decayed buildings.

The hedgehog envelopes himself in leaves, and generally conceals himself in fern-brakes. Hamsters and marmots bury themselves in the ground, and the jumping-mouse of Canada and the United States encloses itself in a ball of clay. At the same time, these singular animals roll themselves together in such a way that the extremities are protected against cold, and the abdominal intestines, and even the windpipe, are compressed, so that the circulation of the blood is checked. Many of them, especially the gnawers, as the hamster and Norway rat, collect, previously to their period of sleep, considerable stores of food, on which they probably live until sleep overpowers them. In this period we observe in the animals, first, a decrease of animal heat, which, in the case of some, is diminished 20°, with others 40° to 50° Fahrenheit; yet it is always higher than the temperature of the atmosphere in the winter months. If these animals are waked during winter, they soon recover their

natural warmth, and this artificial waking does not injure them.

Secondly, animals in a dormant state, breathe much slower and more interruptedly than at other times. Some will remain even a quarter of an hour without any respiration; and animals in this state seldom breathe more than once in a minute. Hence they corrupt the surrounding air much less than if their respiration was free. Of course, the heart moves proportionally slow. With the hamster, it only beats 15 times a minute, whilst, in a working state, it beats 115 times a minute. The irritability of the animals is very low; and hamsters in this state have been dissected, which only now and then gasped for air, or, at least, opened the mouth; and on which sulphuric acid, put on their intestines, had little or no effect.

Marmots can be awakened only by powerful electric shocks. The digestion is also diminished; the stomach and intestines are usually empty; and, even if the animals are awakened, they do not manifest symptoms of appetite, except in heated rooms.

The causes of the dormant state of animals have generally been sought in a peculiar construction of the organs. It is true, that the veins in such animals are usually much wider and larger than in others; hence the arteries can exert comparatively little activity. The great *vena cava* also not merely opens into the right auricle of the heart, but divides itself into two considerable branches; and the thymus gland, which in the fœtus is so large, is also very extensive in this species of animals. The immediate cause, however, producing this torpidity, is mostly, if not entirely, the cold. The animals of this species fall into this sleep in the middle of summer, if they are exposed to a cold temperature; on the other hand, they remain awake during the winter, if they are brought, towards autumn, into a warm room. Yet they fall asleep if the heating of the room is discontinued for some time. In the case of some of them, confined air produces the sleep; thus a hamster may be made to sleep very easily if it is put into a vessel which is buried deep under ground.

Among the birds, some of the swallows are subject to a similar sleep. The swift (*hirundo apus*) is not only found in the crevices of walls, but also in morasses, in a dormant state, during winter; and many have concluded from this that all swallows pass the winter in this state, which is incorrect, as they are known to be birds of passage. Most probably those swallows which have been found in a dormant state, were prevented from emigrating by accident, and became torpid in their retreat, through cold. In a similar way, young cuckoos have been found torpid in the water, though this state is by no means natural to them. With frogs and other amphibious reptiles, the dormant state is very common. As soon as the temperature of the atmosphere sinks under 50° Fah., the number of pulsations of the heart is diminished from 30 to 12 in a minute. If, in this state, food is put into the stomach by force, it remains undigested for a long time. Frogs, serpents, and lizards, kept in artificial cold, may remain for years in this state: hence they have been sometimes found enclosed in stones, in which they have been, perhaps, for centuries. The other lower animals, as snails, insects, &c., are also subject to a similar torpidity. A state of partial torpor takes place in the case of the common bear and the raccoon. The bear begins to be drowsy in November, when he is particularly fat, and retires into his den, which he has lined with moss, and where he but rarely awakes in winter. When he does awake, he is accustomed to lick his paws, which are without hair, and full of small glands; hence the belief that he draws his nourishment only from them. The badger also sleeps the greater part of the winter.

DOUBLING a cape, is to sail round or pass beyond it, so that the point of land shall separate the ship from her former situation, or lie between her and any distant observer.

DOUBLING upon, in a naval engagement; the act of enclosing any part of a hostile fleet between two fires, or of cannonading it on both sides. It is usually performed by the van or rear of the fleet which is superior in number, taking the advantage of the wind, or of its situation and circumstances, and tacking or running round the van or rear of the enemy, who are thereby exposed to great danger.

DOUBLOON; a Spanish coin of the value of two pistoles. (See COIN.)

DOVE-TAILING, in *carpentry*, is the fastening boards together, by letting one piece into another, in the form of the tail of a dove. The dove-tail is the strongest of jointings, because the tenon, or piece of wood which is put into the other, goes widening to the end, so that it cannot be drawn out again.

DOVE-TAIL JOINT, in *anatomy*. This beautiful mode of uniting osseus bodies occurs in various parts of the body; and it is most probable that on that natural species of structure, the carpenter has founded his mechanical process.

DRACHM, the unit of weight and of money among the ancient Greeks, both as a weight and a coin contained six oboli, and was itself the 100th part of a mina, and the 6000th part of a talent. 1. According to the calculations of Wurm, the weight of the Attic drachm is 67.383 grains English Troy weight, and the Attic talent 70 lbs. 6½ oz. The calculation of M. Letronne differs slightly from this. There were several other kinds of drachm and talent in use those of Ægina were the heaviest, the Æginetic talent being equal to 1,000 Attic drachms; the Euboic talent was nearly the same as the Attic; the Rhodian and Egyptian talents were each about one-third of the Attic. Whenever no particular kind is designated, the Attic talent is meant. 2. The principal Grecian coin was the drachm: it was of silver: it was divided, like the weight, into six oboli (silver). The tetradrachm (of four drachms) was called the *stater*. These coins differed much in value in different countries in Greece, and in different ages in the same country. The Attic drachm and stater occur most frequently.

Besides these silver coins, there were also the stater of gold, equal in value to 20 drachms, and the talent of gold, which was used sometimes to designate a quantity of gold equal in *value*, sometimes a quantity of gold equal in *weight*, to the silver talent. It sometimes, also, designates a gold coin, weighing six drachms. In the time of Solon, a sheep could be bought for one drachm, an ox for five. In the time of Demosthenes, a fat ox cost 80 drachms, a lamb, 10.

DRACUNCULI, in *medicine;* small, long worms which breed in the muscular parts of the arms and legs, called Guinea worms, common among the natives of Guinea. The worm is white, round and uniform, resembling white, round tape. It is lodged

between the interstices and membranes of the muscles, where it insinuates itself, sometimes exceeding five ells in length. It occasions no great pain in the beginning; but, at such times as it is ready to go out, the part adjoining to the extremity of the worm, where it attempts its exit, begins to swell, throb, and become inflamed: this generally happens about the ankle, leg, or thigh, and rarely higher. The countries where this distemper is observed are hot and sultry, subject to great droughts, and the inhabitants make use of stagnating and corrupted water, in which it is very probable that the ova of these animalculæ may be contained; for the white people who drink this water are liable to the disease as well as the Negroes.

Drag; a machine employed to search for drowned persons.

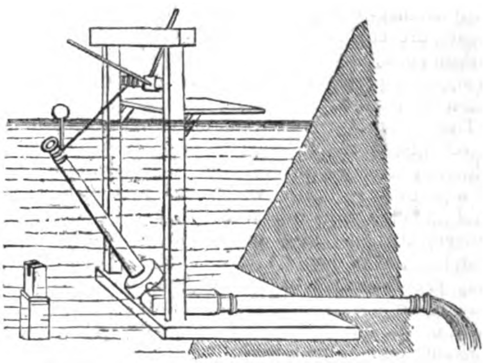
Dragon, in *astronomy*; one of the northern constellations.

Dragon's Blood; a resinous juice, obtained from several plants by incision. It is often very much adulterated, and other substances are substituted; particularly gum Arabic, and gum Senegal, coloured with logwood, &c. Several of these substances may be detected by their dissolving in water, while dragon's blood is nearly insoluble; others require to be submitted to some chemical tests. Madagascar furnishes this resin of a good quality, but so much mixed with foreign substances, that it is little used. Dragon's blood is opaque, of a deep reddish-brown colour, brittle, and has a smooth and shining conchoidal fracture; when in thin laminæ, it is sometimes transparent; when burnt, it gives out an odour somewhat analogous to benzoin; its taste is a little astringent; it is soluble in alcohol, and the solution will permanently stain heated marble, for which purpose it is often used, as well as for staining leather and wood. It is also soluble in oil, and enters into the composition of a very brilliant varnish, which is much esteemed by artists. Its quality may be proved by making marks on paper: the best leaves a fine red trace, and commands a pretty high price. It was formerly in high repute as a medicine, but at the present time is very little used. An astringent resin, obtained from the *eucalyptus resinifera* of New Holland, bears the name of *dragon's blood* in the English settlements in that country.

Dragoon; a kind of light-horseman, of French origin, trained to fight either in or out of the line, in a body, or singly, chiefly on horseback, but if necessary, on foot also. The dragoons were mounted, armed, and exercised as these objects require. They probably took the name of dragoons from the Roman *draconaris*, whose lances were adorned with figures of dragons. Experience proving that they did not answer the end designed, they were hardly ever used in infantry service, and now form a useful kind of cavalry, mounted on horses too heavy for the hussars, and too light for cuirassiers.

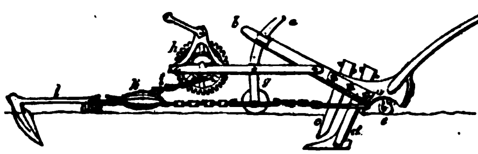
Draining. The inconvenience of an over-moist soil is but little felt in the neighbourhood of the British metropolis. There are, however, many parts of England in which draining becomes a most important desideratum. The first thing to be attended to, is the elevation of the part to be drained: and as in large drains it becomes necessary to keep the channels themselves open, it is adviseable to employ an apparatus similar to that represented in the annexed engraving, to accomplish this object.

Now, if we suppose the place to be drained situated in the neighbourhood of the sea, it will not be adviseable to admit a free communication at all times; but it requires a free passage of water at stated periods, for the purpose of cleansing the drain, and at different heights. The diagonal tube supported by the rope coiled round the cylinder, may be readily placed at any required angle. When we wish the water in the drain not to exceed a certain height, we have only to regulate the winch accordingly.



We have thus briefly noticed the drain on a large scale. A very simple mode of draining land, which is wet merely from the retentive nature of the soil, and which has been practised with success, consists in adding to the felly of a six-inch cart wheel, a piece of wood, upon which is a triangular rim of iron. That side of the cart containing this prepared wheel, is then loaded, till the piece of iron indents the soil to the depth of six or eight inches. These furrows are made in lines from five to ten yards asunder, the grass is merely pressed down, and not destroyed, and they generally grow up in the course of the year. They should, therefore, be made annually, at the approach of winter; but the work is so easily executed, that a single person, with two old horses, will go over from ten to twenty acres in eight hours.

Draining Plough. This is a very important agricultural implement, of which we give a diagram.



We may suppose a case in which its powers would be indispensable. It becomes necessary to cut a trench for the passage of water; and the furrow being too deep for the common process, the anchor or hook, *l*, is inserted in the ground. We have thus a fixed point for resisting the action of the pulley, *k*. If power be now applied to the handle at top, it communicates motion to the wheel, *h*, with an enormous increase of power, and the acting portions of the plough, *c d*, are forced through the soil. The arrangement at *a b c*, enables the conductor to give the required depth to the furrow. It will be obvious that the pulley, *g*, by resting on the ground, tends to diminish friction.

Draught; the depth of a body of water necessary to float a ship; hence a ship is said to draw so many feet of water, when she is borne up by a column of water, of that particular depth; for instance, if she requires a body of water, whose depth is equal to twelve feet, to float or buoy up a ship on its surface, she is said to draw 12 feet of water; and, that this draught may be more readily known, the feet are marked on the stem, and stern post, from the keel upwards.

Draughts; a game played on a chequered board, with twenty-four pieces, which by angular movements, are enabled to take each other, according to certain rules, until one of the parties has lost all his men, or is placed in a situation to lose them all, when the game is at an end.

Drawback, in *commerce;* an allowance made to merchants, on the re-exportation of certain goods; which in some cases consists of the whole, in others of a part of the duties, which had previously been paid upon the importation. A still more equitable arrangement than that of drawbacks, is, to allow the merchant, who imports any commodity, which he may probably wish to export again, to deposit it in the public warehouses, giving a bond for the payment of the duties, should he dispose of it for home consumption. This is called *bonding,* and is allowed to a considerable extent in this country.

Drawing, considered as a distinct branch of art, is the elder sister of painting, and in the course of time became connected with geometry. It is the art of representing by means of lines upon a flat surface, the forms of objects, and their positions and relations. The attempt to imitate, by lines, the forms which we see in nature, is the commencement of all drawing. According to a Greek tradition, drawing and sculpture took their rise together, when the daughter of Dibutades drew the outline of the shadow of her lover upon the wall, which her father cut out and modelled in clay. We can distinguish, in the earliest attempts at drawing, different epochs, which are found in almost all nations:—1. Objects were delineated only with rude, shapeless lines. 2. In order to make such drawings more striking to the eye, the sketch was filled up with black, or some other colour, and then the eyes, eyebrows, nose, mouth, and hair were marked with white upon the dark surface. To all these figures the name was attached, and in general, explanatory words, such as we find upon all the old vases.

This custom was continued by the Greeks, even in the most flourishing period of the art of drawing among them; for the figures of the great picture of Polygnotus, at Delphi, were designated by such inscriptions. In the 3rd epoch, an attempt was made to give animation to pictures, by representing the different colours of the drapery; but, as yet there was no attempt at perspective. In this manner Helen and Andromache embroidered tapestry, as described in the poems of Homer. In the 4th period, the want of prominence in the figures was remarked. Ardices and Telephanes (probably fictitious names) began, by drawing lines in the back-ground, to produce the appearance of shadow, and to give prominence to their figures. In later times, Polidoro di Caravaggio delineated in this way many frescoes in Rome, where he used only a single colour, but produced the shading by lines drawn thus, in the manner called *hatching.* These works are called *al sgrafito* or *peindures hachées.* This manner of drawing, however, was very hard. Philocles and Cleanthes invented the *monochrome,* or picture with one colour. In the *monochrome,* the colour used was mixed with white, so that this resembled the style now called *en camayeu.* This was the first step from drawing to proper painting, which is distinguished by having the back-ground of the picture filled.

The Greeks were very careful and particular in their instruction in drawing. Pamphilus, the teacher of Apelles, wished his pupils to remain with him ten years. There were three stages of instruction: in the first, firmness of hand and of stroke was obtained, and the learners drew with styles upon tablets covered with wax; in the second, fineness and delicacy of stroke was studied, while the learner laboured with the style upon smooth tablets, made of box-wood, and sometimes upon membranes, or upon the skins of wild beasts, properly prepared, and covered with wax. In the third stage, freedom and ease were to be acquired; here the pencil was used instead of the style, and with it black or red sketches were drawn upon white tablets, or white sketches upon black tablets. The tablets used were covered either with chalk or gypsum.

Line-drawing was carried to the highest perfection, and was the glory of the greatest masters. The rivalship of Apelles and Protogenes in such lines, drawn with distinguished delicacy and skill, and displaying a master's hand, is well known. This fineness and clearness of outline is also the chief merit of the celebrated vase painters. Something hard and dry was found in the pictures executed on such outlines, and it may well be maintained that this manner of drawing, through the influence of the Byzantine school on the west of Europe, gave rise to the dry and meagre style of the old Italian as well as of the old Dutch school.

When we consider the art of drawing as it exists at the present time, we perceive that there are three distinct kinds of drawing—with the pen, with crayons, and with Indian ink, or similar substances. Artists sometimes employ coloured and sometimes white paper; in the former case, the lights are produced by white crayons; but in the latter case, they are produced by leaving the paper uncovered. The drawings with the pen have always something hard and disagreeable, yet they give steadiness and ease to the hand, and are peculiarly serviceable to landscape painters. There are two different ways of drawing with the pen; either the drawing is darkened on the shaded side with lines, or the outline only is given by the pen, and the shades are delicately touched in with Indian ink.

This mode is peculiarly adapted to architectural drawings. The crayon drawings are the most common, and the most suitable for beginners, because any faults can be effaced or covered over. Artists make use of black, as well as of red crayons; and, when the ground is coloured, they produce the light by means of white crayons. If the crayon is scraped, and the powder rubbed in with little rolls of paper or leather, the drawing becomes exceedingly delicate and agreeable, though its outline is deficient in strict precision. This manner, which from the French name of the rolls used, is also called *à l'estompe,* is peculiarly suitable for large masses, and shades, and *chiaro-scuro,* and for producing a harmonious effect of light. There are also crayon drawings, where the

principal colours of the objects painted are delicately sketched with coloured pencils; these are peculiarly suitable for portraits. To this kind of drawings belong likewise those made with lead and silver pencils, upon paper and parchment, which are suitable for the delicate delineation of small objects. In some cases, drawings of this description are softly touched with dry colours. There is another style of drawing, in which Indian ink, or sepia and bistre intermingled with carmine and indigo, are used. The lights are produced by leaving the white surface uncovered. This mode produces the finest effect, and is very much used in the representation of all kinds of subjects.

There are various classes of drawings, as sketches, studies, academy figures, cartoons, &c. *Sketches* are the first ideas of the subject of a picture, thrown off hastily, to serve as the basis of a future drawing. They are made with charcoal, with the pen, or the pencil. To the rapidity of their execution may be ascribed the animation perceptible in the sketches of great masters, of which there are rich collections. *Studies* are copies of single parts of subjects, made either after life or from models; as heads, hands, feet, sometimes also whole figures. Drawings from skeletons and anatomical preparations, those of drapery, animals, plants, flowers, scenery, &c., are also called by this name. *Academy figures* are drawn from living models, who stand in academies of fine arts and other establishments, intended for the education of artists. The models, male and female, of all ages, are placed in different situations and attitudes, on an elevated spot, by lamp-light. The pupils stand round and draw, under the direction of professors. Experienced painters and sculptors likewise continue to draw from living models, either in private or in company. The most perfect figures, of course, are selected. In order to study drapery, a figure of wood, with moveable limbs, is placed so that the student can draw from it.

Cartoons are drawings on gray paper, of the same size as the paintings which are to be copied from them. These are, for instance, large oil paintings, fresco pictures, &c. Artists make use, also, of other means, in order to transfer the outlines of a painting upon another canvass, if they wish to copy very faithfully. If the copy is to be on a larger or a smaller scale than the original, it is customary to place on each canvass frames of wood, the space enclosed by which is divided, by means of threads, into quadrangular compartments. The compartments on the original are larger or smaller than the others, as the case may be. The artist then draws in each square of his canvass what he finds in the corresponding square in the original. If the copy is intended to be precisely of the same size with the original, the outlines are often traced through a black gauze, from which they are afterwards transferred by pressure to the canvass of the copy. This, it is true, does not give any distinct forms, but it indicates precisely the spot where every object is to be placed, which saves much time.

If the intention is to copy the outlines of the original exactly, it is necessary to make a *calque*, that is, a paper saturated with varnish, and quite transparent, which is put on the painting; the outlines are drawn; then the paper is blackened with crayon on one side, put on the new canvass, and the outlines are followed by some pointed instrument, and thus transferred to the canvass. It is evident that it is never allowable to take a copy in this way from very valuable pictures. The sketches of great masters are always valued very highly, because they show most distinctly the fire and boldness of their first conceptions. But for this very reason, because their excellence depends on the freedom with which they are thrown off, it is far more difficult to make copies from them than from finished paintings. The great schools in painting differ quite as much in respect to drawing as in respect to colouring. The style of drawing of the old Italian school is as hard, dry, and meagre as that of the old German school. The defects of the former are more often redeemed by beautiful forms and just proportions, whilst in the latter a meaning is frequently expressed which inclines more to poetry than to art.

At a later period, the Roman school became, in Italy, through the influence of Raphael's exquisite sense of the beautiful and expressive in form, and through the study of the antique, the true model of beautiful drawing. The Florentine school strove to excel the Roman in this respect, and lost, by exaggeration, the superiority which it might, perhaps, otherwise have gained from its anatomical correctness, and deep study of the art. The masters of the Florentine school often foreshorten too boldly. In the Lombard school, delicate drawing appears through enchanting colouring; but perhaps it is more true to nature and feeling than to scientific rules. The Venitian school, in reference to the other schools of Italy, has many points of resemblance, good and bad, with the Dutch school, in reference to Germany.

In the Venetian school, the drawing is often lost in the glow and power of the colouring; and it is very often not the nobleness of the figures and ideas in the drawing, but the richness, boldness, and glowing nature of the painting, which delight us. The French school was, in Poussin's time, very correct in drawing; and he was justly called the *French Raphael.*—At a later period, the style of this school became *maniéré*. David introduced again a purer taste in drawing, and a deep study of the antique. This study of the antique, together with the precision of their drawing, are the distinguished characteristics of the modern French school.

In Germany, there cannot be said to be any general style of drawing peculiar to her artists. The many distinguished artists of that country have formed themselves individually, by the study of nature and works of art; and whilst some of the most celebrated painters are distinguished for correct drawing, others are reproached for want of it, in some of their finest pictures. On the whole, their drawing is not so correct as that of the French. Many young German artists unfortunately consider the *naïveté* of the ancient masters of their country as beauty, and strive to imitate it.

Having thus furnished our readers with a brief view of the mechanical processes in drawing, and an outline of the peculiar features of the principal schools; it will be proper to examine the progress of design, commencing with simple lines. This is a subject that was admirably treated by Mr. Reinagle, in his Lectures, delivered in the Royal and London Institutions.

Fuseli thus describes the peculiar features of this important branch of the fine arts:—" Of design, the

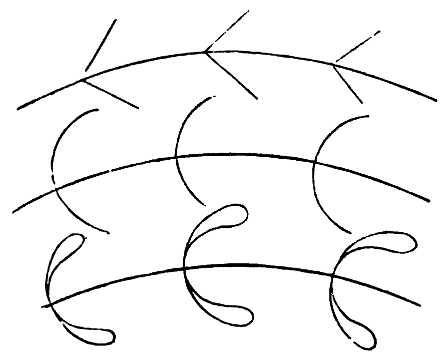
element is correctness and style; its extinction, incorrectness and manner. On the first principle of correctness, or the powér of copying and drawing with precision the proportions of any object singly, or in relation with others—as it may be considered in the light of an elementary qualification, without which none should presume to enter himself a student of the academy—I should perhaps forbear to speak, did I not consider it as the basis of design, and were I not apprehensive that from the prevalent bend of the reigning taste, you do not lay on it all the stress you ought; and that, if you neglect the acquisition of the power to *copy* with purity and precision any given object, you will never acquire that of *imitating* what you have chosen for your model. Our language generally confounds—or rather those who use it, when they speak of the art—the two words *copy* and *imitation*, though essentially different in their operation, as well as their meaning. An eye geometrically just, with a hand implicitly obedient, is the requisite of the former, without all choice, without selection, amendment, or omission; whilst choice, directed by judgment and taste, constitutes the essence of imitation, and raises the humble copyist to the noble rank of an artist. Those who have stopped short at the acquisition of the former faculty, have made a means their end, have debased the designer to the servile though useful draughtsman of natural history: and those who have aspired to the second, without gaining the first, have substituted air for substance, and attempted to raise a splendid fabric on a quicksand: the first have retarded the progress of the art; the second have perverted its nature: each have erred, to prove that the coalition of both is indispensable."

Every thing deserving the title of beautiful, and every grand object, assume an outline of definite character; the former in undulating lines of elliptic curves, and grandeur in angular dispositions of figure. Lines of motion, on the contrary, assume a curved direction. The first means of combining straight lines so as to please the eye, without creating any geometrical figure, is the radiating principle. Our eye not only can tolerate that union of lines, but receives the impression as pleasing in character; while all lines parallel to each other, being right lines, and viewed as a flight of steps, or pile of rods producing an opposite effect on the observer, are disagreeable.

Upon the former principle it is, that the rays of the sun, and rays of light generally, are so attractive and beautiful. It is from this circumstance that right lines, drawn in an inclined position to the plane of a picture, derive an interest from the angles engendered through the imagination. To follow up the principle by regular steps, and to open a clear view of the laws of beauty in lines, we may trace an inclined right line, with a regular set of right angles upon it, like the stems of leaves on each side. This exhibits no sort of beauty, nor any other advantage than mere combinations of formal angles. We may then draw an inclined line, as before, with similar angular projecting stems, to which should be added elliptic curves on the upper side of each branch, and the form of a leaf is produced. The next step is an incl ned line, having oval curves upon it. Both these possess principles approaching to beauty, by progressive advances in combination and original structure. An inclined line, with the oval curves upon it; to which are added elliptic curves on the upper side of each stem. This addition is a new advance towards beauty. A more perfect principle of beauty, having an elliptic stem with oval branches rising from it, will readily be conceived by the student.

If to this, the principle of gradation be given, by a scale of increase from the top to the bottom of the projecting stems; and if there be superadded the external contour of a lengthened egg, like the form of a sage-leaf, we shall, step by step, advance into the region of beautiful character in exterior design.

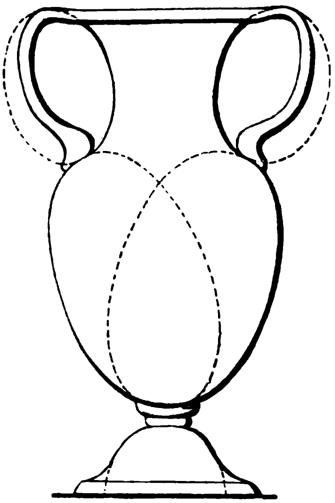
In the subjoined engraving we give three forms; in the latter is seen the elliptic stem with the oval branches rising from it, to which small serpentine additions are made, expressing a leaf.



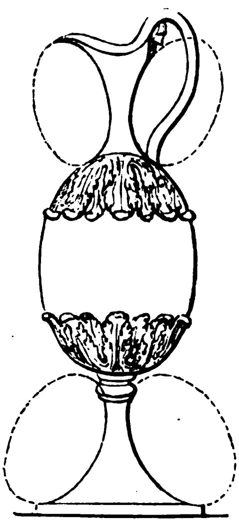
Of all the three diagrams to which we have adverted, the last abounds with the greatest portion of beautiful lines, and is indisputably the most agreeable and beautiful. Combinations are like numericals: many of these forms, placed together with judgment and discretion, will attract us from the larger proportion of beauty that meets the eye at once, like a head of beautiful hair: one hair, however gracefully bent, cannot impress us like an entire lock of the hair; nor will this curl charm us as the whole will on the human head. We owe to construction and combination all our pleasurable feelings of beauty: no person is allured by a single species of objects: but a thousand, or a million, arouses our anxious notice. Thus, the last diagram of the elliptic stem, and foliage upon it, exhibits, by the continuity of curved lines, the greatest approach to beauty, of any of its predecessors. These preliminary designs open the way for richer combinations. Curved lines of various quantities of convex and concave, drawn at random, without expressing or forming any sort of figure, please our eye more than any set of right lines similarly distributed. Quantity and variety are absolutely necessary to the production of perfect beauty; equalities being unfriendly to that symmetry which accords with nature. The combinations of the oval may be varied to an extraordinary extent. The vases represented in the engravings, though very dissimilar in appearance, are both the result of these combinations.

Here it may be proper to state, for the benefit of the student, that the most perfect collection of vases in this country are now deposited in the British Museum. They are placed in a room by themselves, and are of the greatest use to the artist. While upon this subject, we would remark, that as a general principle, too little attention is given by our young students to that splendid depository, as it is perfectly accessible to all.

The first, resembling a Greek vase with handles, is composed of seven parts. The body has four parts; the foot, or pedestal, one; the neck two. The handles are regulated in the position and projection by lines drawn from the bottom of the vase, through the ovals which compose the outline of the two sides, and passing through the transverse diameter. These handles are made from an oval that is the length of half the line of the transverse diameter. The skeleton of angles that govern the shape of this vase, is a very pretty figure of itself. The form does not proceed from any caprice or irregularity, but is consistent with rational organization, and symmetrical proportions. The other vase, represented beneath, exhibits an Hebe cup, with a handle which presents a totally different appearance in form to the previous one.



It is proportioned by similar principles: the large disc makes the body, inclining right and left upon the end of the oval. The neck and leg are both made from the smaller oval disc; the dotted lines to the ovals of the leg, sufficiently show the fact. The handle and concave lip of the cup, are made by an application of the same disc. The altitude contains four parts, the body two parts, the leg one part, and the neck one other part; the handle rises one-eighth above. Every portion of this figure is created by the two discs previously named. The foliage rises from below and descends from above, one-fourth of the whole height of the body to the commencement of the concavity of the neck, where the beading runs round. It has been remarked, that by adhering to regular proportional quantities of 1 and 2, 3 and 5, 2 and 5, 7 and 2, &c., and using elliptic discs or curves, very great beauties are derived.



The motion of ships at sea is described in gentle elliptic curves; the wings and plumage of birds assume the oval and elliptic curves; all the fibres of their feathers have that form; some flattened, others more rounded: the pine-apple and numberless fruits have all an oval character of outline. Many take the character of eggs, pointed at one end, and large and blunt at the other extremity. The leaves of trees have the oval shape more than any other; the bend of the branches, and the whole external form of many trees is oval. There is no form of created things which may not be found to correspond in all its dependant shapes, to ovals and ellipses of various discs; even objects which at first sight seem to contradict the possibility of meeting this system.

The Greek artists so confined themselves to certain rules and principles of unerring consequences, in the production of beauty, grace, or grandeur in their figures, that all their compositions depended upon the same species of rule and order. It is much to be regretted that fashion is in all countries the destroyer of taste; that it unfits the mind for fixed principles; that where it dominates, *there* taste will be always fluttering and never settle, nor have a sure dominion. The Greeks do not appear to have suffered themselves to be diverted from a pure course of design in their studies, and, as such, arrived at a very high degree of perfection in most scientific pursuits, by following sure principles as their guides, and by never abandoning a path traced by nature, and matured by the most sublime philosophy.

Pursuing our path in the subject of design, we at once come to the human form. The whole of our readers have, no doubt, seen, in the elementary treatises on drawing, the series of curves which form the human structure; to illustrate this, however, in the readiest way, we may turn to that great master of design, Raphael.

In this beautiful group, representing the Holy Family, the principle of the circle advancing to an oval is beautifully portrayed. In childhood, the circle predominates, but at a later period of life the face is elongated, and now though much of the prettiness begins to pass away, it is succeeded by the markings of a higher degree of intellect. The deeper and more powerful workings of the mind succeed to the infantile simplicity which marked the first dawning of reason.

In the beautiful curves which composed the vases first noticed, the forms must of necessity be the same under all circumstances; hence it will be obvious that the difficulty increases very considerably when we come to the varying characters, ages, and passions of mankind. The mode of delineating the human form, will, however, be discussed and illustrated under PORTRAITURE.

There is more of skilful design essential to a right arrangement of the folds in the drapery of a figure than the young artist is apt to imagine. The ancients excelled in *picturesque*, but not in *natural* drapery.—An example of the latter will be found in the figure beneath, designed by Flaxman.

We have heard of sculptors who design their drapery by laying layers of wet and flexible clay over the figure they are about to execute, but by such a process as that, little of real excellence could be produced. The ancient masters appear to have arranged their draperies as the upholsterer nails his curtain, in faultless form, and perfect order—nothing was left to chance. Now, to give a piece of drapery the slightest claim to a natural character, its whole arrangement must be that of chance; and no person can examine the simply natural masses, shown in the above figure, without at once observing the vast inferiority of the ancients under this head.

We must not, however, forget that this simplicity may easily degenerate into vulgarity, and poverty of conception. We may take as an example, the exquisite piece of drapery introduced by Chantrey, in his bust of the late Sir W. Scott. Now this has been copied by other inferior artists, and they have attempted, by the aid of a small handkerchief, or towel, to give the massive folds and beautiful contour of the original, and the consequence has been failure of the worst kind. Great depth of finish is not essential to good drapery—but just conception, and an acquaintance with the mechanical character of different fabrics.

In proof of what we have now been advancing, we may take one of the most beautiful groups probably in existence, and to which our artist has done ample justice. Cupid and Psyche possess in a peculiar degree, all the graces of the antique school. It has in this respect also its peculiar faults.

The waist of the male figure is encircled by a double row of drapery, forming unbroken lines of small plaits — now this is neither natural, nor yet picturesque. The drapery of Pscyhe much resembles that of the Caryatides, and is as quaint as it is unnecessarily indelicate. Flaxman and Canova, among modern sculptors, and Retsch and Frank Howard, in the pictorial art, stand highest in the power of embodying what is beautiful in the ancient school with the more natural character of real life. The dramatic illustrations of the latter form a distinct era in art. (See GROUPING and PORTRAITURE.)

DRAWING A PATTERN, in *weaving*, expresses the preparation of the figures with which the workman enriches his stuff, or silk, and which he copies after some painter, or eminent draughtsman; as in diaper, damask, and other flowered silk and tapestry, and the like. We are now enabled to manufacture pattern goods in this country, fully equal to, if not superior to the foreign artizans. In undertaking such kinds of figured stuffs, it is necessary, before the first stroke of the shuttle, that the whole design be represented on the threads of the warp; we do not mean in colours, but with an infinite number of little packthreads, which, being disposed so as to raise the threads of the warp, let the workman see, from time to time, what kind of silk is to be put in the eye of the shuttle, for woof. This method of preparing the woof is called reading the design, and reading the figure, which is performed in the following manner: A paper is provided considerably wider than the stuff, and of a length proportionate to what is intended to be represented thereon. This they divide lengthwise, by as many black lines as there are intended threads in the warp; and cross these lines, by others drawn breadthwise, which, with the former, make little equal squares: on the paper thus squared, the draughtsman designs his figures, and heightens them with colours, as he sees fit. When the design is finished, a workman reads it, while another lays it on the simblot.

To read the design, is to tell the person who manages the loom, the number of squares or threads comprised in the space he is reading; intimating, at the same time, whether it is ground or figure. To put what is read on the simblot, is to fasten little strings to the several packthreads, which are to raise the threads named; and thus they continue to do till the whole design is read.

Every piece being composed of several repetitions of the same design, when the whole design is drawn, the drawer, to re-begin the design afresh, has nothing to do but to raise the little strings, with slip-knots, to the top of the simblot, which he had let down to the bottom; this he is to repeat as often as is necessary till the whole be manufactured.

The ribbon weavers have likewise a design, but far more simple than that now described. It is drawn on paper with lines and squares, representing the threads of the warp and woof. But, instead of lines, whereof the figures of the former consist, these are constituted of points only, or dots, placed in certain of the little squares, formed by the intersection of the lines. These points make the threads of the warp that are to be raised, and the spaces left blank denote the threads that are to keep their situation: the rest is managed as in the former.

Dropsy; a preternatural collection of serous or watery fluid in the cellular substance, or different cavities of the body. It receives different appellations, according to the particular situation of the fluid.—When it is diffused through the cellular membrane, either generally, or partially, it is called *anasarca;* when it is deposited in the cavity of the cranium, it is called ***hydrocephalus;*** when in the chest, *hydrothorax*, or *hydrops pectoris;* when in the abdomen, *ascites;* in the uterus, *hydrometra;* and within the scrotum, *hydrocele.*

The causes of these diseases are a family disposition thereto, frequent salivations, excessive and long continued evacuations, a free use of spirituous liquors (which never fail to destroy the digestive powers), scirrhosities of the liver, spleen, pancreas, mesentery, and other abdominal viscera; preceding diseases, as the jaundice, diarrhœa, dysentery, phthisis, asthma, gout, intermittents of long duration, scarlet fever, and some of the *exanthemata;* a suppression of the accustomed evacuations, the sudden striking in of eruptive humours, ossification of the valves of the heart, polypi in the right ventricle, aneurism in the arteries, tumours making a considerable pressure on the neighbouring parts, permanent obstruction in the lungs, rupture of the thoracic duct, exposure for a length of time to a moist atmosphere, laxity of the exhalants, defect in the absorbents, topical weakness, and general debility.

The first of these species which we shall describe is *ascites* (from a sack or bottle; so called from its bottle-like protuberancy), or dropsy of the belly, a tense, but scarcely elastic, swelling of the abdomen from accumulation of water. Ascites is often preceded by loss of appetite, sluggishness, dryness of the skin, oppression at the chest, cough, diminution of the natural discharge of urine, and costiveness. After the swelling has commenced, it increases until the whole belly becomes uniformly swelled and tense. The distension and sense of weight vary somewhat with the position of the body, being greatest on the side on which the patient lies. As the collection of water becomes more considerable, the difficulty of breathing is much increased, the countenance exhibits a pale and bloated appearance, an immoderate thirst comes on, the skin is dry and parched, and the urine is very scanty, thick, and high-coloured, and deposits a lacteritious sediment. The pulse is variable, being sometimes considerably quicker, sometimes slower than is natural. The operation of tapping should be performed only where the distension is very great, and the respiration or other important functions impeded; and it will often be best not to draw off the whole fluid at once. Great care must be taken, also, to keep up a sufficient pressure, by a broad bandage over the abdomen, as even fatal syncope has arisen from neglect of this. The contraction of the muscles will be promoted by friction. The remedies for this disease are cathartics, diuretics, gentle friction of the abdomen with oil, &c. Tonic medicines, a nutritious diet, and, if the complaint appears giving way, such exercise as the patient can take without fatigue, with other means of improving the general health, ought not to be neglected.

Another species of dropsy, is called *anasarca.* It is occasioned by a serous humour, spread between the skin and flesh, or rather by a general accumulation of lymph in the cellular system.

This species of dropsy shows itself at first by a swelling of the feet and ankles towards the evening, which, for a time, disappears again in the morning. The tumefaction is soft, and inelastic, and, when pressed upon by the finger, retains its mark for some time, the skin becoming much paler than usual. By degrees, the swelling ascends, and occupies the trunk of the body; and, at last, even the face and eyelids appear full and bloated: the breathing then becomes difficult, the urine is small in quantity, high-coloured, and deposits a reddish sediment; the belly is costive, the perspiration much obstructed, the countenance yellow, and a considerable degree of thirst, with emaciation of the whole body, prevails. To these symptoms, succeed torpor, heaviness, a troublesome cough, and a slow fever. In some cases, the water oozes out through the pores of the cuticle; in others, being too gross to pass through them, it raises the cuticle in small blisters; and sometimes the skin, not allowing the water to escape through it, is compressed and hardened, and is, at the same time, so much distended, as to give the tumour a considerable degree of firmness. In some few cases, the disease goes off by a spontaneous crisis, by vomiting, purging, &c. Where the quantity of fluid collected is such as to disturb the more important functions, the best mode of relieving the patient, is to make a few small incisions with a lancet, not too near each other, through the integuments on the fore and upper part of each thigh; the discharge may be assisted by pressure.

In the use of issues or blisters, there is some risk of inducing gangrene, especially if applied to the legs; and the same has happened from scarifications with the cupping iustrument. Absorption may be promoted by friction, and bandaging the parts, which will, at the same time, obviate farther effusion; but most powerfully by the use of different evacuating remedies, especially those which occasion a sudden considerable discharge of fluids. Emetics have been often employed with advantage; but it is necessary to guard against weakening the stomach by the frequent repetition of those which produce much nausea.—Cathartics are of much greater and more general utility. Diuretics are universally proper. Digitalis is often a very powerful remedy. Opium, and some other narcotics, have been occasionally useful. In the use of diuretics, the patient should not be restricted from drinking freely. It is very desirable to promote evacuation by the skin. Sometimes much relief is obtained by promoting perspiration, locally,

by means of the vapour bath. Mercury has been much employed.

Regular exercise, such as the patient can bear (the limbs being properly supported, especially by a well-contrived laced stocking), ought to be enjoined, or diligent friction of the skin, particularly of the affected parts, employed when the tumefaction is usually least, namely, in the morning. The cold bath, duly regulated, may also, when the patient is convalescent, materially contribute to obviate a relapse.—The next species of dropsy which we shall consider is *hydrocephalus, hydrocephalom, hydrencephalus;* dropsy of the brain, dropsy of the head. It is sometimes of a chronic nature, when the water has been known to increase to an enormous quantity, effecting a separation of the bones of the head, and an absorption of the brain. Pain in the head, particularly across the brow, stupor, dilatation of the pupils, nausea, vomiting, preternatural slowness of the pulse, and convulsions, are symptoms of this disease. Hydrocephalus is almost peculiar to children, being rarely known to extend beyond the age of twelve or fourteen; and it seems more frequently to arise in those of a scorfulous and ricketty habit than in others. It is an affection which has been observed to pervade families, affecting all or the greater part of the children at a certain period of their life; which seems to show that, in many cases, it depends more on the general habit, than on any local affection, or accidental cause. The disease has generally been supposed to arise in consequence either of injuries done to the brain itself, by blows, falls, &c., from scirrhous tumours or excrescences within the skull, from original laxity, or weakness in the brain, or from general debility and an impoverished state of the blood.

With respect to its proximate cause, very opposite opinions are still entertained by medical writers, which, in conjunction with the equivocal nature of its symptoms, prove a source of considerable embarrassment to the young practitioner. When recoveries have taken place in hydrocephalus, we ought, probably, to attribute more to the efforts of nature than to the interference of art. It is always to be regarded as of difficult cure. The treatment should be prompt and active. The inflammatory action should be lessened, and then absorption promoted. After taking some blood by bleeding or by leeches, the torpid bowels are to be evacuated by some active cathartic, and their activity kept up, in the progress of the complaint, by calomel, or some other mercurial preparation. Mercury also contributes powerfully to rouse the absorbents.

After the bowels are cleared, some evaporating lotion is to be applied to the shaved scalp, and the antiphlogistic regimen observed. Sudorific medicines will generally be proper, assisted by the warm bath. Blisters may be applied to the temples, behind the ears, or to the nape of the neck. If the progress of the disease is arrested, the strength is to be established by a nutritious diet and tonic medicines.

Drosky; a kind of light, four-wheeled carriage, used by the Russians. It is not covered, and its side seats contain a greater or less number of persons. The lower wheels are covered with wings, which keep off the mud.

Drosometer; an instrument for ascertaining the quantity of dew which falls. It consists of a balance, one end of which is furnished with a plate fitted to receive the dew, the other containing a weight protected from it.

Drowning may be defined as death caused by immersing the exterior opening of the respiratory tube in a liquid. Actual death is often preceded by apparent death (*asphyxia*); and it is possible, if this state has not continued too long, to resuscitate a person apparently drowned. This circumstance has led to careful investigations of the nature of drowning, and also, in the neighbourhood of seas and large rivers, to the erection of public institutions for the resuscitation of persons apparently drowned. This kind of death furnishes, likewise, a difficult subject for medical jurisprudence, and gives occasion to the inquiry, whether a body found in the water was actually drowned, or whether life was lost in some other way; and great attention has been paid to the marks of this sort of death, which are to be found upon the body. But, notwithstanding all this pains, much uncertainty still hangs over the subject. This remark is true, as well of the manner in which death is the consequence of immersion, as of the signs of having been drowned, and the means of resuscitating from apparent death.

If a person voluntarily immerses his head in water, he perceives a roaring in his ears, a tickling in his nose, a pressure upon his breast, and a kind of stupid feeling. If a man, unable to swim, falls into the water, he instinctively makes every exertion to escape from it; he holds his breath, moves his head up and backwards, lays hold of every solid body which presents itself, and even grapples at the bottom of the water. These struggles continue a longer or a shorter time, according to the strength and presence of mind of the unhappy subject: at last, he sinks, exhausted, becomes unconscious, strives to breathe, draws in water, and life is gone. When the body is taken from the water, it is commonly found to be very cold; the limbs are stiff, the countenance distorted, livid, and often pale, the eyes half open, the pupils enlarged, the mouth filled with foam, the breast and region of the upper stomach expanded. Sometimes the body is still warm, though it cannot be reanimated, the countenance blue and distorted, the veins of the neck much swollen. This takes place when a person is drowned in alcohol, or in marshy or warm water, or when in a state of intoxication, or with a full stomach, or a heated body, a person falls overboard. On opening the body of a person who has been drowned, the epiglottis is found to be raised, bloody foam appears in the windpipe and bronchial passages, the lungs are soft and distended, a large quantity of black fluid blood is collected in the right, and less in the left cavity of the heart, a little water is in the stomach, and the vessels of the brain are swelled with blood. Death is sometimes caused by suffocation and want of air, and sometimes as in apoplexy: in the latter case, it happens very speedily, and a little water is sufficient to produce it, if the person falls upon his face. In this case, when the body is opened, the foam in the windpipe is wanting, and the vessels of the head are fuller. The various constituents of the water, such as irrespirable gases, contribute also to modify and complicate the mode of death.

The following are the methods of treatment recommended by the Humane Society for the recovery of persons in a state of suspended animation. As drowning is, probably, the most frequent accident by which animation is suspended, we give all the rules

of the society here, and shall refer them from FREEZING, HANGING, &c. to this article.

One of the first rules of the society is, that if a person be taken from the water, apparently drowned, send quickly for medical assistance; but do not delay the following means:—Convey the body carefully, with the head and shoulders supported in a raised position, to the nearest house. Strip the body, and rub it dry; then wrap it in hot blankets, and place it in a warm bed, in a warm chamber. Wipe and cleanse the mouth and nostrils. In order to restore the natural warmth of the body, move a heated covered warming-pan over the back and spine; put bladders or bottles of hot water, or heated bricks, to the pit of the stomach, the armpits, between the thighs, and to the soles of the feet; foment the body with hot moistened flannels; but, if possible, immerse the body in a warm bath, as hot as the hand can bear without pain, as this is preferable to the other means for restoring warmth; rub the body briskly with the hand; do not, however, suspend the use of the other means at the same time. In order to restore breathing, introduce the pipe of a common bellows (where the apparatus of the society is not at hand) into one nostril, carefully closing the other and the mouth; at the same time drawing downwards, and pushing gently backwards, the upper part of the windpipe, to allow a more free admission of air; blow the bellows gently, in order to inflate the lungs, till the breast be a little raised; the mouth and nostrils should then be set free, and a moderate pressure made with the hand upon the chest. Repeat this process till life appears. Electricity is to be employed early by a medical assistant. Inject into the stomach, by means of an elastic tube or syringe, half a pint of warm brandy and water, or wine and water. Apply sal volatile or hartshorn to the nostrils.

If apparently dead from intense cold, rub the body over with snow, ice, or cold water. Restore warmth by slow degrees; and after some time, if necessary, employ the means recommended for the drowned. In these accidents, it is highly dangerous to apply heat too early.—If apparently dead from hanging, in addition to the means recommended for the drowned, bleeding should early be employed by a medical assistant.

If apparently dead from noxious vapours, &c., remove the body into a cool, fresh air. Dash cold water on the neck, face, and breast, frequently. If the body be cold, apply warmth as recommended for the drowned. Use the means as above recommended for inflating the lungs. Let electricity (particularly in accidents from lightning) be early employed by a medical assistant.—If apparently dead from intoxication, lay the body on a bed with the head raised; remove the neckcloth, and loosen the clothes. Obtain instantly medical assistance, as the treatment must be regulated by the state of the patient; but, in the mean time, apply cloths soaked in cold water to the head, and bottles of hot water, or hot bricks, to the calves of the legs and to the feet.

If apparently dead from apoplexy, the patient should be placed in a cool air, and the clothes loosened, particularly about the neck and breast. Bleeding must be early employed by a medical assistant; the quantity regulated by the state of the pulse. Cloths soaked in water, spirits, or vinegar and water, should be applied to the head, which should be instantly shaved. All stimulants should be avoided.

In cases of *coup de soleil*, or strokes of the sun, the same means are to be used as in apoplexy. On restoration to life, a tea-spoonful of warm water should be given; and then, if the power of swallowing be retained, small quantities of warm wine, or weak brandy and water, warm; the patient should be kept in bed, and a disposition to sleep encouraged, except in cases of intoxication, apoplexy, and *coup de soleil*. Great care is requisite to maintain the restored vital action, and, at the same time, to prevent undue excitement. The treatment recommended by the society is to be persevered in for three or four hours. It is an erroneous opinion that persons are irrecoverable because life does not soon make its appearance; and it is absurd to suppose that a body must not be meddled with or removed without the permission of a coroner.

DRUM. Instruments which produce a sound by means of a tightly extended skin, are common in almost every part of the world. The tambourine is found amongst most nations; the ancients called it *tympanum*. All these instruments are used both for profane and sacred purposes. But the peculiar use of the drum for military purposes seems to have been introduced among the Europeans in the time of the Crusades. There are very many different kinds of drums in the East, described by Niebuhr.

The kettle drum, the bass drum, tambourine, and other kinds, are all common in the East. The drum, as a military instrument, is used both to beat the march and to give signals. No man, who has not experienced it, can imagine the exciting power of the drum. The fatigued and exhausted soldier is at once animated by its sound; and in battle it preserves order, and inspires courage in a body attacking *en colonne*. The French drummers perform admirably, and, under Napoleon, a great number were attached to each battalion. A drum which has acquired historical celebrity, is that which, by the order of Zisca, was covered with his own skin, that he might still aid in battle, where he had so often commanded, even after he had become blind.

DRUNKENNESS, considered in a *physical* point of view, is that derangement of the animal economy, which is produced by drinking spirituous or fermented liquors.

The effects of fermented liquor on the animal economy, arises principally from its *stimulating* power, or the power which it possesses of exciting the muscular parts to an increased rapidity and strength of action, as well as the nervous and mental qualities to an unusual degree of acuteness. When the animal functions are carried on with languor and feebleness, from whatever cause, the general sensations of the body are uneasiness, sometimes to a degree of pain. Thus, after long fasting, want of sleep, fatigue, or disease, this condition of the frame exists, and prompts us instinctively to the employment of some stimulus, as food, tepid, or fermented drink, the warm bath, &c. The immediate effect of such stimula, especially of fermented liquors, is the diffusion of a grateful sensation throughout the body; the languor and listlessness of the previous state are superseded by a general pleasurable feeling of warmth, energy, and self-command, accompanied by an indescribable tranquillity and complacency of mind; the countenance is enlivened with a glow of animation, in consequence of the free circulation through the cutaneous blood-vessels, and the renewed energy

occur in which entire deafness, taking place at the age of eighteen, so affected the articulation, that the individual was no longer intelligible, even to his friends. This result will not be prevented by any degree of hearing less than we have mentioned; for most deaf and dumb persons can hear some sounds; and some can distinguish the high from the low, who perceive no difference in articulations.

Only a few mutes are found who owe this defect to feebleness of mind, or to any imperfections in the organs of speech. These remarks show the fallacy of the idea, that the want of speech is owing to the want of mental capacity—a prejudice which has been cherished by the usual name of *deaf and dumb*, which we hope, for this reason, as well as for euphony, will be changed for that of *deaf mute*, which may be employed both as a noun and an adjective.

The number of deaf mutes varies materially in different countries, and situations, and classes of men. In the United States, partial examination leads to the belief that there is one deaf mute for every 2000 inhabitants. In some countries of Europe, there is one for every 1500 or 1700; in others, one for every 1000; and, in some locations, the proportion is three or four times as great as this. The proportion has been found greatest in some districts or portions of cities remarkable for the dampness and impurity of the air. The greater number of these unfortunate persons is found among the poorer classes; and hence it has been supposed, that the defect is frequently caused by the want of the necessary supplies and attentions during infancy or disease.

A large number of deaf mutes are born deaf; but it appears from the reports of a large asylum, that more than half the persons admitted lost their hearing by accidents or diseases, chiefly fevers and diseases of children.

The immediate causes of ordinary dumbness are known to be various. In some few cases, it is owing to an imperfection or injury of some part of the organs of speech, and, of course, is irremediable. In other cases, it seems to arise from obstructions in the external or internal passage of the ear. Cures have sometimes been effected by removing these obstructions by means of instruments or injections, especially, of late, by doctors Itard and Deleau, of Paris, who throw injections into the Eustachian passage, by means of a flexible tube passed through the nostrils. Doctor Deleau is reported, by a committee of the French Institute, to have relieved or cured several deaf persons, by injections of *air*, long continued; but he does not estimate the probable number of cures in deaf mutes at more than one in ten. Perforation of the tympanum is sometimes useful in rendering it more easy to remove obstructions which may be discovered; and, for this purpose, it is deemed important to perform it by means of circular discs, closing with a spring, which remove a portion of the membrane, and leave a permanent opening. In other cases, and in the usual mode, this operation often produces great suffering, and has not been generally useful.

In 81 cases of perforation at Groningen, in Holland, only three were permanently relieved, and these in a very partial degree. In the greater proportion of deaf mutes, no defect is visible, and no applications appear to be useful. In a number of anatomical examinations of deceased deaf mutes, at Paris, the ear was found perfect in all its parts. The inference has therefore been made, that the disease consists in a paralysis of the auditory nerve—a conclusion which seems to be sustained by the fact, that, in some cases, a cure has been effected by actual cautery on the back of the head, and that galvanism has sometimes given temporary relief. According to the estimates we have mentioned, the number of deaf mutes in the United States is about 6000, and in Europe not less than 140,000; all of whom, by their deafness (which we see is usually beyond the reach of remedies), are shut out from the intercourse of society, and the ordinary means of acquiring knowledge. The situation and character of such a large class of unfortunate persons are subjects of deep interest.

The necessity of communication, and the want of words, oblige the deaf mute to observe and imitate the actions and expressions which accompany various states of mind and of feeling, to indicate objects by their appearance and use, and persons by some peculiar mark, and to describe their actions by direct imitation. In this way, he and his friends are led to form a dialect of that universal language of attitude, gesture, and expression, by which the painter and the sculptor convey to us every event of history, and every feeling of the soul—which becomes a substitute for words in the hands of the pantomimic actor, and which adds force and clearness to the finest effusions of the orator—in other words, the natural *sign language*.

The terms of this language are of two kinds—the descriptive and the characteristic or indicative signs. Descriptive signs involve an account (more or less complete) of the appearance, qualities, and uses of an object, or the circumstances of an event, for the purpose of description or explanation, and must, from their nature, be varied, like a painting, only by the point of view from which the objects are described, or the capacity and accuracy of the person that describes. The indicative signs, on the contrary, which are employed in common conversation, are usually mere abbreviations of these, involving a single striking feature of the person, or object, or event; as an elephant is indicated by its trunk, a flower by its fragrance, or a town by a collection of roofs.

The signs of persons are usually conventional, and derived from some feature, or mark, or habit, but often from an accidental circumstance in dress, &c., which struck the deaf mute on first seeing the person, and is still referred to when it no longer exists. It is obvious that, in this class of signs, there is great room for dialects, according to the situation, capacity, and habits of observation of the individual, and that much may be done for its improvement, by a proper selection.

The sign language, like every other, varies in its extent with the intelligence, the wants, and the circle of ideas of those who use it. When employed by an insulated deaf mute, it will usually exhibit only the objects of the first necessity, and the most common impulses, like the language of a savage tribe. When his ideas expand, from age or observation, he will find new modes of expressing them; and, when his education is begun, an intelligent deaf mute will often express ideas in this language, for which it is difficult to find expressions in words. When a number of deaf mutes are brought together in a single institution, selections and combinations of their various dialects are formed; the best are gradually adopted by all; and a new and more complete form of the

language is the result—as in nations collected by civilization. This process, carried on for half a century in the institution of Paris, and some others in Europe, under the observation and direction of intelligent men possessed of hearing, has produced a language capable of expressing all the ideas we convey by articulate sounds, with clearness, though not always with equal brevity, and which those who value it least admit to surpass speech in the force with which it communicates the feelings and states of mind.

Like painting (as Condillac observes), it has the immense advantage of presenting a group of ideas at once, which lose much of their force and beauty, by being detailed in the successive words and artificial arrangements of written language. The eye, the hand, the whole body, speak simultaneously on one subject; the representation changes every moment, and these peculiarities, with the elliptical form of expression which is adopted in conversation, give a rapidity to communication by the sign language, which, on common subjects, among those familiar with it, surpasses that of speech. If we remark the new shades of meaning given to the same words, by the varying attitude and general expression of the speaker, and the accuracy with which a nice observer will discover, in these signs, the thoughts, and feelings and intentions, even of one who wishes to conceal them, we shall find reason to believe that they are capable of conveying the most delicate shades of thought.

Generic and abstract terms, as their objects do not exist in nature, have no corresponding terms of equal clearness in the sign language; and the abbreviated manner in which we express relations by conjunctions, prepositions, relatives, and inflections, can only be imitated by adopting similar conventional signs, which do not easily fall in with the idiom of the language. In these respects, therefore, the sign language wants the algebraic brevity and accuracy which are found in artificial languages, and which render these so invaluable as mediums of thought, and instruments of philosophical investigation; at the same time, it is capable of describing what is conveyed by these forms, with an accuracy at least as great as that of words, by circumlocution and example.

It is worthy of remark, that the order of expression, in the sign language, is that which we term *inverted*—the subject before the quality, the object before the action, and, generally, the thing modified before the modifier. This language, in its elements, is to be found among all nations, and has ever been the medium of communication between voyagers and the natives of newly-discovered countries. It is employed by many savage tribes to supply the paucity of expression in their language, or to communicate with other tribes, as in the Sandwich Islands, and in North America. Among the Indians of the western territory of the United States, Major Long found it an organised language, employed between tribes who spoke different articulate languages. The accounts received from himself, as well as his work, show that it corresponds, almost precisely, with that in use in the school of Paris; and a Sandwich Islander, who visited the American asylum for deaf mutes, gave a narrative of his life in the sign language, which was perfectly understood by the pupils. If testimony be wanting that it still retains its universal character, in its cultivated form, we may state that an intelligent writer, who acquired it in this form, observes that he has employed it, or seen it employed, with success, in communicating with an American Indian, a Sandwich Islander, a Chinese, and the deaf and dumb in England, Scotland, France, Germany, Switzerland, and Italy, and in various parts of the United States.

The more lively nations of Europe, belonging to the Celtic race, the French and Italians, &c. make great use of this language, in connection with words, and, sometimes, even without them. The more phlegmatic people of the Teutonic race, in England and Germany, are so little disposed to it, and so much less able to acquire or understand it, that they regard it as a species of affectation or buffoonery in their southern neighbours; and to this circumstance it is probaby owing, that it has been so extensively rejected, among these nations, as an auxiliary in the education of the deaf mute.

The natural condition of the deaf mute may be inferred from the account we have given of his language. It is obvious that the mere loss of hearing cannot, in itself, diminish the natural vigour of any other faculty, either of body or mind. He must, however, be destitute of all ideas of sounds; but these form so small a part of the circle of our ideas, in comparison with those derived from sight, that they cannot seriously affect him. His conceptions, derived through the medium of sight, are usually more accurate than ours, his recollections more vivid, and his powers of description more striking, because his attention is more undivided. His discrimination of feeling and character is often intuitive, and he frequently divines the subject of conversation from the appearance of the speaker. The tremendous part of his misfortune is the interruption of communication with his fellow-men, on all subjects except the primary wants and impulses, which arises from the imperfect character of his sign language, in an uneducated state. His ideas are very much limited to the objects and events he witnesses, and the exterior relations of things; and he is shut out from all the knowledge derived from history and tradition. Past ages, distant countries, a future world, a Deity, are all beyond his reach. In regard to the combination and application of the ideas which he acquires, he is still in the state of nations in the infancy of society, and cannot be aided or directed by others, in his efforts to reason.

After extensive observation and inquiry, we cannot hear of or find a single instance in which a person, born deaf, has conceived of a First Cause, from a view of the works of nature, without education. They describe themselves as looking at these objects like the brutes. Even those whose friends have made great efforts to communicate religious truths, seldom have an idea of the Deity, as a Creator or Benefactor; and a deaf mute at Chartres, in France, who had been taught to perform all the rites of the Catholic church, and was deemed very devout, on receiving his hearing, stated that he had no conception of any thing but the external forms of religion. Conscience, in them, derives all its light from the observation of the conduct of others, and the instinctive impulses; but recognises no invariable law, and often leaves these unfortunate persons to commit gross crimes, without any sense of guilt. In short, they are enveloped in intellectual and moral darkness, in the midst of the clearest light.

Mention is made of deaf mutes in the writings of

Pliny; and they were declared, by the Code of Justinian, incapable of civil acts. No attempts appear to have been made to give them instruction, until the latter part of the 15th century, when we are merely told by Agricola, professor of philosophy at Heidelberg, in Germany, of a deaf mute who had been instructed. In the middle of the 16th century, Pascha, a clergyman of Brandenburg, instructed a daughter, who was a deaf mute, by means of pictures. But the first effort for this interesting object, of which we have a distinct account, was made by Pedro de Ponce, a Benedictine monk, of the Spanish kingdom of Leon, who instructed four deaf mutes, of noble families, to write and speak, in 1570.

In 1620, John Bonet, another Spaniard, published the first book known on this subject, containing an account of the method which he adopted in a similar course of instruction, and accompanied by a manual alphabet, from which that now in use at Paris was derived.

In 1659, the instruction of deaf mutes was attempted, with apparent success, by Doctors Holder and Wallis, both of whom published accounts of their methods. At about the same time, Van Helmont, in Holland, published an ingenious treatise on the manner of forming articulate sounds, the principles of which, he says, he had applied with success to the instruction of a deaf mute. In 1691, John Conrad Amman, a Swiss physician in Leyden, published a similar work; but he and his predecessors appear to have devised and executed their plans without any knowledge of those who had previously attempted the same thing.

In 1704, the methods published in Spain, England, and Holland, were first applied, in Germany, by Kerger, apparently with much ingenuity and success, and some improvements. He was soon followed by a number of labourers in the same field, of whom Arnoldi appears to have been the most distinguished. In 1743, the practicability of instructing deaf mutes was first publicly demonstrated in France, by Pereira, a Spaniard, before the Academy of Sciences, who gave their testimony to its success. About the same time, this branch of instruction was attempted in France, by several others, among whom Deschamps, Ernaud, and Vanin were best known. In 1755, Heinicke in Germany, De l'Epée in France, both of whom were led to feel an interest in deaf mutes thrown accidentally in their way, formed each an independent system of instruction, established the first institutions for the education of deaf mutes, at Paris and Leipsic, and may be justly regarded as the founders of the two great schools, into which the instructors of the deaf mutes have since been divided. In 1764, Thos. Braidwood, of Edinburgh, devised a system of instruction, in which, as in that of Heinicke, articulation was the chief object. Both these persons, for a long time, refused to communicate their inventions, except for a compensation, and under the seal of secrecy; and their principles have scarcely extended beyond the countries in which they originated.

De l'Epée devoted his fortune and his life to the instruction of his pupils, and the gratuitous communication of the art to all who would learn it; and, in consequence of his efforts and instructions, schools were founded by Silvestri at Rome, Stork at Vienna, Guyot at Groningen, and Ulrich in Switzerland, which still exist in the hands of their disciples. The system of De l'Epée was materially improved by Sicard, his pupil and successor in the institution of Paris, who is admitted to have surpassed his master, and to rank with him as one of the greatest benefactors of the deaf mute. Towards the close of the last century, Assarotti, of Genoa, established, by his own benevolent efforts, an institution which ranks among the first in Europe, and formed a system of instruction, based, indeed, upon that in Sicard's works, but involving important improvements, which entitle him to be considered the founder of the Italian school.

The objects to be accomplished in the education of a deaf mute, are to teach him an entire language, and to give him all that mass of moral, religious, and ordinary knowledge that is necessary for him, as a social and immortal being, for which, in other children, 12 or 15 years of constant intercourse with society, and much study, are deemed necessary; all this is to be done in six, and often even in three years. It is obvious that, to accomplish this, some method, more rapid in its results than the ordinary one, must be adopted. The earlier instructors of the deaf mute usually had only one, or a very few pupils, and have given us *hints* for instruction, rather than a system.

The first account which we have of the reduction of this art to a regular and permanent form, is in the works of Heinicke and De l'Epée. Heinicke, like many of his predecessors, considered the want of speech as the great misfortune of the deaf mute, and made it the great object of instruction to teach him to articulate, in order to aid the progress of his own mind, as well as to enable him to communicate with others in this manner. We are told by the successor of Heinicke in the Liepsic school, that the following "are and were the views and principles of Heinicke and his disciples:"—that "we think in articulate words, and cannot think in written words;" "that written words can never lead to the development of ideas, in children born deaf;" and that "no freedom in thought, or in the use of language, can be produced without articulation, either by signs or by written language."

If it were credible that sounds were more allied to abstract ideas than objects of sight are; if we could forget that we often have ideas for which we cannot easily find words, the facts we have stated concerning the language of signs, and the capacity of several hundred pupils, educated merely by signs, in the English and American institutions, to read and write, and converse and reason, prove the entire fallacy of these views; and the argument *ab ignorantia* cannot be adduced, at this day, on that subject, without disgrace. Those who follow this system admit the use of the sign language in the early stages of instruction, but seek to banish it as early as possible, considering it as a rude language, incapable of improvement, and which retards the expansion of the pupil's mind, and renders it less necessary for him to attend to written language. They adopt the methods of the early instructors, in waiting for occasions to teach words and explain phrases. They rely upon repeating the word or phrase in the appropriate circumstances, and in questions and answers, as the means of making it understood, rather than on direct explanation, or examples presented by the sign language. Too many of this school forget one of the fundamental maxims of Heinicke—"first ideas, then words"—and occupy the pupil for a long time with mere mechanical articulation. In one school, months are passed in the mere study of names attached to

pictures, without the least attempt to excite or enlighten the mind by means of signs; and usually a year is passed, at a period of life when most of the mental faculties are ripe for development, in the mere exercise of memory (in learning names of objects, and qualities, and actions), which only requires the powers of an infant, and would be aided, instead of retarded, by the expansion of the mind, as the experience of the other schools fully proves.

Religious instruction is rarely attempted in this school before the second year, or until it can be given in words, from the belief that it cannot be given correctly by signs; and in the school of Leipsic, it is even deferred to the third year. The attention of De l'Epée, and other instructors of the same views, was called especially to the intellectual and moral wants of the deaf mute; and they deemed it most important first to develope his powers, and cultivate his feelings; and, next, to give him such a knowledge of written language as is indispensable to the acquisition of knowledge, and the communication of his wants. They found the only medium of conveying truth, or explaining terms, in the sign language which we have described; and thus having formed the basis of a permanent system, they employed it in its natural state, to explain the first simple terms. They discovered that it was capable of extension, and they preserved and cultivated it, as we have mentioned, as a language intelligible to the pupil, by which they could always refer to any objects of thought or feeling, physical, intellectual, or moral, and thus form original explanations of new words, and avoid the error which might arise from the imperfection of previous explanations. Words they considered as arbitrary signs, and De l'Epée maintained, that the instruction of the deaf mute, like that of a foreigner, ought to consist in a course of translation, and retranslation, from the known to the unknown language. To aid in this process, he added a series of methodical and conventional signs, founded on analogy, for the particles and inflections of language. These were used chiefly in instruction, in order to render the translation complete, as well as to indicate the character and meaning of the connectives. He does not appear to have practised fully upon his own principles, but occupied himself too exclusively with the intellectual improvement of his pupils, and with single words, and seems to have despaired of enabling them to use language, in its connection, except in a mechanical manner.

Sicard endeavoured to complete the plan of his master, by the improvement of the signs employed; and to him and his pupils we owe, more than to any others, the perfection which this language has attained. He also endeavoured to avoid the error of De l'Epée, by explaining the theory of grammar, and the formulas of the various species of propositions, and, in this way, was led into a course of metaphysical and philosophical lessons, which later instructors have found too extensive and too little practical.

According to the system adopted under his direction, the first year was occupied with a vocabulary of names, of adjectives, and of verbs in three simple tenses, with simple religious and other narratives in the sign language. It was only in the second year, that words were shown, in their connection, in short phrases; the pronouns, prepositions, and the full inflection of the verbs, were taught, and religious instruction given, in written language. In the third and fourth years, the organs, senses, and operations of the mind, and the theory of sentences, were explained, original description and definitions required, and in the fourth year books were put into the hands of the pupils. Throughout the course, public lectures were given, in which written accounts of Bible history, and religious truth, were explained in the sign language; but no devotional exercises in this language were ever connected with them, or practised by the pupils.

The American system has been materially modified in the school of Paris itself, and in several others on the continent of Europe, which adopt the same principles. As the American system of instruction, devised by Mr. Gallaudet, without any knowledge of others, except that of Paris, on which it is founded, comprises most of these improvements, with some others of great importance, peculiar to itself, we cannot do better, within the limits allowed us, than to describe this as we have found it, in his own statement, and in the American Asylum. Mr. Gallaudet has combined the fundamental principle of Heinicke —"first ideas, then words"—with that of De l'Epée —that "the natural language of signs must be elevated to as high a degree of excellence as possible, in order to serve as the medium for giving the ideas clearly, and explaining them accurately." He has added another of no small importance—that, as words describe rather the impression, or states of mind produced by external objects, than those essential qualities which are beyond our reach, the process of learning them would be facilitated by leading the pupils to reflect on their own sensations and ideas; and he states, as the result of his experience, that, among deaf mutes of equal capacities, "those who can be led to mark or describe, with the greatest precision, the operations of their own mind, uniformly make the most rapid progress in the acquisition of written language, and of religious truth." A leading object, therefore, in connection with the first lessons, in which sensible ideas are presented and named, is to establish a free communication with the pupil, in the sign language, in reference to his feelings and thoughts, as excited by the objects which he sees, or the events of his own life. He easily comprehends those of others, and is thus led to learn the names of the simple emotions and acts of the mind. Hence he is brought to think of an invisible agent, which we term the *soul*, as the feeling and percipient being; and, by a natural transition, is led, by the use of signs alone, to the Great Spirit, as the first cause; to his character, as our creator and benefactor; and to a knowledge of his law and our future destiny. In this manner, the deaf mutes in the American asylum (and, we presume, in others derived from it) are made acquainted with the simple truths of religion and morality in one year; a period in which, in most European institutions, they are scarcely advanced beyond the knowledge of the sounds, and the names of sensible objects, qualities, and actions, or the most common phrases.

By communicating this instruction in the natural sign language, pupils, whose inferior capacity or advanced age would not allow them to acquire enough of written language to receive religious truth through this medium, have been early prepared to enjoy its blessings and hopes, and feel its sanctions as a restraint upon their conduct, which renders their

government more easy, while it aids them in the formation or correct notions.

Another plan, which is not known to have been ever employed before its introduction by Mr. Gallaudet, in 1817, was to conduct the daily and weekly devotional exercises by signs; and the deaf mutes have been thus taught to address the Father of their spirits in their own natural language, and have been admitted to the new privilege of social worship.

In applying the first principles to the course of instruction in language, an important improvement has been made, by combining words into phrases as early as possible, and thus teaching the pupil how to use them. The idea of each phrase is first explained by the sign language, and then translated into words, and then retranslated by the pupil into his own language. The process is carried on for more difficult words, and the phrases are lengthened until they become narratives. The acquisition and use of the connectives are aided by the methodical signs of De l'Epée and Sicard. The pupil is called upon, at intervals, to express his own ideas in writing, and to explain by signs what is written by others. An important additional improvement is "to employ the pupil, as early as possible, in the study of books written in an easy style, explained by signs when necessary," so as to lead him, by his own and often by his unaided efforts, to become acquainted with the arrangemement of words, and the idioms of written language. He is led gradually to infer the rules of grammar from a series of examples, instead of committing them to memory; and the theory of language is reserved for the later years of instruction, when the pupil is familiar with its practical use.

The methods of instruction in the elements of arithmetic, geography, and history, do not differ materially from those usually employed, except that much aid is derived from explanatory signs; and experiments, made in some of the schools both in England and France, prove that those may be usefully employed to illustrate various subjects to persons possessed of hearing.

While the instructors of the school of De l'Epée and Sicard unite in denying that articulation is necessary to the deaf mute, as a means of mental development, they admit its great value as a supplement to intellectual education, if it be attainable. But they differ as to the practicability and expediency of attempting to teach it generally. Of its great practical value in darkness, or in cases of sudden danger, there can be but one opinion; and it is certainly important that every deaf mute should be taught some cry of distress, or perhaps a few words for such occasions; for some do not know how to use their voice even to this extent.

The power of articulating, even imperfectly, may also be of great importance to the deaf mute, where ignorance in writing is combined with a phlegmatic inattention to signs, in those among whom he is situated. But that it is not indispensable, as an ordinary means of communication, is proved by the fact, that the pupils of the French and American schools, find no difficulty in making themselves intelligible to those around them, either by writing or signs, on all necessary subjects.

Articulation is learned and recollected by the deaf mute, as a set of movements and sensations in the organs of speech. It is taught by pointing out to the pupil the powers of the vowels and consonants, and the position of the lips, teeth, and tongue, and by making him feel with his hand, or a silver instrument, all the perceptible movements and vibrations of the throat and interior organs, which are requisite for their pronunciation. He is then required to imitate this position, and to force a quantity of air from the lungs, sufficient to produce the sound, and is taught to read the articulations of others, by observing the position of the organs and the countenance. The facility of doing this, will depend much upon the pliability of the organ of speech, and the nature of the language to be learned. We observed, as would naturally be supposed, that the soft and regular language of Italy, in a climate where we have other evidence of a superior pliancy of the vocal powers, was acquired with tolerable success, by a short period of daily practice. But the harsh and gutteral sounds of the northern languages, and the irregularity which is found in the pronounciation of some of them, present several additional difficulties, which are perhaps increased by the frequent diseases of the vocal organs, produced by a cold climate. Those instructors who attempt to teach all their pupils these languages, are usualy compelled to make it a constant and individual exercise, and to make and to demand efforts painful to the teacher, and pupil, and spectator, with only a partial success. Of a number of speakers, whom we have seen and heard of, in various countries, thus taught, few would have been intelligible to a stranger so readily as by signs; and their tones were extremely disagreeable. On the other hand, we have seen a few deaf mutes who are capable of speaking in a manner perfectly intelligible, and of reading from the lips and countenance, what was said by others. They were such, however, as either retained some remnant of hearing, or had been the subjects of individual instructions for a series of years. We presume the truth lies in that middle course, now adopted by the school of Paris, and by some advocates of articulation, who have had an opportunity of observing it in all its forms. They believe that, by that portion of the pupils of every institution, whose organs are pliable, and who have some remnant of sensibility, either in the external or internal ear (those termed *demi sourds* in the Paris school), the acquisition may be made with a degree of ease and perfection, which renders it a desirable and important branch of instruction for such portion of the pupils, in every institution. They are equally convinced, that to attempt to teach articulation to those entirely destitute of sensibility in the ear, or who cannot exercise the organ of speech without difficulty or pain, is a useless labour, and may produce disease in the pupil; as more than one instance proves. On the last point, some have maintained that the exercise of the lungs is important to the pupil, while others have declared the contrary. We believe here, also, much will depend on individual organization, and that the general question will be modified much by the climate, and nature of the language to be taught. Most of the schools for deaf mutes employ a manual alphabet, for the more rapid communication in words: in this country usually made with both hands, and elsewhere with one. This alphabet, with writing, on paper and in the air, and the use of natural and conventional signs, are found adequate means of communication for those who cannot acquire articulate language.

DWARFS. In ages when knowledge depends mostly on tradition, it is natural for the human mind to people the world with a thousand imaginary beings. Such are dragons, giants, and dwarfs; all of which have some foundation in reality, and afford amusement to the imagination, even after experience has corrected the belief in the reality of their marvellous character. We need hardly say, that the pygmies of the ancients, and the Quimos, whom Commerson tells us that he discovered, are as fabulous as the renowned Lilliputians. The dwarfs which actually exist are deviations of nature from her general rule; and the term *dwarf* is a vague one, as we cannot say how small a person must be, to be so called. There is no instance on record of dwarfs distinguished for great talents. Their figures are sometimes perfectly well proportioned. They have generally one trait in common with children—a very high opinion of their own little person, and great vanity.

The Romans used dwarfs for several purposes; sometimes in gladiatorial exhibitions, on account of the ridiculous contrast which they afforded to their opponents. Towards the end of the middle ages, and even, in some countries, as late as the beginning of the last century, dwarfs were a fashionable appendage to the courts of European princes, and the families of the nobles. Who does not recollect the numerous pictures of those times, with a Negro or a dwarf in the back ground? They seem to have been great favourites with the ladies of the family. They were sometimes, also, used as jesters. Peter the Great carried this fancy for dwarfs to a great extent. He assembled individuals of this kind from all parts of his empire, and ordered the famous marriage of the dwarfs. At the court of Constantinople a number of dwarfs are always maintained, as pages. Those who happen to be, at the same time, deaf and dumb, and have been mutilated, are particularly valued, and reserved for the sultan.

DYEING is a chemical art, and consists in fixing upon cloths of various kinds any colour which may be desired, in such a manner as that they shall not easily undergo any alteration, by the agents to which the cloth is ordinarily exposed. The chief materials or stuffs to be dyed are wool, silk, cotton, and linen; of which the former two are more easily dyed than the latter.

Wool, in its preparation for dyeing, requires to be cleansed, by scouring, from a fatty substance, called the *yolk*, which is contained in the fleece. This is done by means of a weak alkaline solution, which converts the yolk into soap. Urine is commonly employed, on account of its cheapness; the ammonia it contains being sufficient to remove the grease.

Silk, when taken from the cocoon, is covered with a kind of varnish, which, because it does not easily yield either to water or alcohol, requires also the aid of a slight portion of alkali. Much care is necessary, however, in this operation, since the silk itself is liable to be corroded and discoloured. Fine soap is commonly used; but even this is said to be detrimental; and the white China silk, which is supposed to be prepared without soap, has a lustre superior to the European.

The preliminary process of washing is intended to render the stuff to be dyed as clear as possible, in order that the aqueous fluid, to be afterwards applied, may be imbibed, and its contents adhere to the minute internal surfaces.

Another preparation, and one which constitutes, in reality, an important part of the dyeing process, consists in applying to the stuff, a material to which it adheres; and afterwards the desired colour is obtained by the application of another substance. We might dye a piece of cotton black, by immersing it at once in ink; but the colour would be neither good nor durable, because the particles of precipitated matter are not sufficiently comminuted to enter the cotton, or to adhere to it firmly. But, if the cotton be soaked in an infusion of galls, then dried, and afterwards immersed in a solution of sulphate of iron, the acid of galls being everywhere diffused through the fabric, it will receive the particles of oxide of iron, at the very instant of their transition from the fluid to the solid state; by which means a perfect covering of the black, inky matter will be applied in close contact with the surface of the most minute fibres of the cotton.

The name of *mordant* is applied to those substances which unite with the different stuffs, and augment their affinity for the various colouring matters. There exists a great number of mordants; some, however, are very feeble in their activity, while others are attended with too much expense for common stuffs; some alter the colours which they are intended to combine, or modify their shades: hence it results, that there are but a small number which can be employed. These are alum, acetate of alumine, muriate of tin, nut-galls, &c.

The mordant is always dissolved in water, into which the stuffs to be dyed are plunged. If the mordant be universally applied, over the whole piece of goods, and this be afterwards immersed in the dye, it will receive a tinge over all its surface; but if it be applied only in parts, the dye will strike in those parts only. The former process constitutes the art of *dyeing*, properly so called; and the latter the art of printing cottons, or linens, called *calico-printing*.

In the art of printing piece goods, the mordant is usually mixed with gum or starch, and applied by means of blocks or wood engravings, in relief, or of copper plates, and the colours are brought out by immersion in vessels filled with suitable compositions. The latter fluids are termed *baths*. The following are the processes usually adopted, when alum is the mordant employed:

1. *Alum mordant for silk.* Into water containing the 60th part of its weight of alum, at the ordinary temperature of the air, the silk is plunged, and allowed to remain for 24 hours, when it is withdrawn, drained, and washed. If the liquid is warmed, it is found that the silk absorbs less of the mordant, and that, of course, it combines less easily with the colouring matter, besides losing, in part, its natural gloss.

2. *Alum mordant for wool.* When it is wished to combine wool with this mordant, after its cleansing has been effected, it is plunged into a boiling solution, composed of 8 or 900 parts of water, and 25 of alum, where it is allowed to remain during two hours; when it is taken out, suffered to drain, and washed.

Frequently a little cream of tartar is added in this process, in order to engage the excess of acid in the alum, as well as the portion arising from a slight decomposition of the alum by the oily matter of the wool.

3. *Alum mordant for cotton, hemp, and flax.* This operation is effected by plungnig the body to be

imbued with this mordant into water slightly warmed, and which contains one quarter of its weight of alum, and leaving it 24 hours, at the common temperature of the air; when it is withdrawn, washed, and dried. The cotton will be sufficiently imbued with the mordant, if allowed to remain in the solution only 7 or 8 minutes, pressing it a little, without twisting it, however, on taking it out, and not immersing it in the colouring bath until 12 or 15 hours after. In all alum mordants for wool, the alum of commerce may be employed; but when silk or cotton is to be dyed, especially if the colours are bright, it is necessary to make use of the alum of Rome, or of that which is equally pure; that is to say, of alum which does not contain above 1-500th of its weight of sulphate of iron; otherwise there will be a great quantity of oxide of iron adhering to the fabric, which will affect the shade we desire to obtain. The colouring matters to be transferred to the various stuffs are either soluble or insoluble in water. When they are soluble in water, which is most generally the case, they are dissolved in it at a boiling temperature; and the material to be dyed, after having been duly prepared, and impregnated with the mordant, is plunged into it, where it is allowed to remain for a certain time, and at a temperature varying with the nature of the stuff. When, on the contrary, the colouring matter is insoluble in water, its solution is effected in some other fluid, and the article to be coloured (prepared as in the former case, with the exception that the application of the mordant is omitted) is immersed, and the colouring matter is precipitated by the addition of a third body. Silks are dyed at a temperature which is gradually increased from 86° to 175° Fahr. If the bath is heated above 86°, at the commencement of the process, the effect of the mordant is diminished, and the desired shades of colour will not be produced. For the same reason, in dyeing hemp and flax, the temperature should not exceed 97° Fahr. Cotton and woollens may be dyed at a boiling heat.

Various mechanical contrivances are made use of in immersing the different materials to be dyed into the colouring solution, so as to cause all their parts to be equally affected at the same time. As soon as they are withdrawn from the colouring bath, they are washed in a large quantity of water, in order to deprive them of those particles of colouring matter that are merely superficial.

The following are the dye-stuffs used for producing *fast* colours: 1. *Black.* The cloth is impregnated with acetate of iron (iron liquor), and dyed in a bath of madder and logwood. 2. *Purple.* The preceding mordant, diluted, with the same dyeing bath. 3. *Crimson.* The mordant for purple, united with a portion of acetate of alumine, or red mordant, and the above bath, 4. *Red.* Acetate of alumine is the mordant, and madder is the dye-stuff. 5. *Pale red,* of different shades. The preceding mordant, diluted with water, and a weak madder bath. 6. *Brown of Pompadour.* A mixed mordant, containing a somewhat larger proportion of the red than of the black, and the dye of madder. 7. *Orange.* The red mordant, and a bath, first of madder, and then of quercitron. 8. *Yellow.* A strong red mordant, and the quercitron bath, whose temperature should be considerably under the boiling point of water. 9. *Blue.* Indigo, rendered soluble and greenish-yellow coloured, by potash and orpiment. It recovers its blue colour by exposure to air, and becomes firmly fixed upon the cloth.

An indigo vat is also made by diffusing indigo in water, with quicklime and copperas. These substances are supposed to act by deoxidizing indigo, and, at the same time, rendering it soluble. *Golden dye.* The cloth is immersed alternately in a solution of copperas and lime-water. The protoxide of iron, precipitated on the fibre, soon passes, by absorption of atmospherical oxygen, into the golden-coloured deutoxide. *Buff.* The preceding substances, in a more dilute state. *Blue vat,* in which white spots are left on a blue ground of cloth, is made by applying to these points a paste, composed of a solution of sulphate of copper and pipe-clay, and, after they are dried, immersing it, stretched on frames, for a definite number of minutes, in the yellowish-green vat, of one part of indigo, two of copperas, and two of lime, with water. *Green.* Cloth dried blue, and well washed, is imbued with the acetate of alumine, dried, and subjected to the quercitron bath. In most of the above cases, the cloth, after receiving the mordant paste, is dried, and put through a mixture of cow-dung and warm water. It is then put into the dyeing vat or copper. The foregoing colours are also produced from decoctions of the different colouring woods; but, as they possess but little fixity when thus formed, they are denominated the *fugitive* colours. 1. *Red* is made from Brazil wood and peach wood. 2. *Black.* A strong extract of galls and deuto-nitrate of iron. 3. *Purple.* Extract of Logwood and the deuto-nitrate of iron. 4. *Yellow.* Extract of quercitron bark, or French berries, and nitro-muriate of tin. 5. *Blue.* Prussian blue and solution of tin. Fugitive colours are thickened with gum tragacanth, and are sometimes sent to market with out being washed.

DYNAMETER, measurer of increase, *augomètre;* an instrument for measuring the magnifying power of telescopes. It consists of a small tube, with a transparent plate, exactly divided, which is fixed to the tube of a telescope, in order to measure exactly the diameter of the distinct image of the eye-glass.

DYNAMICS is the science of moving powers, or of the action of forces on solid bodies, when the result of that action is motion. *Mechanics,* in its most extensive meaning, is the science which treats of quantity, of extension, and of motion. Now, that branch of it which considers the state of solids at rest, such as their equilibrium, their weight, pressure, &c., is called *statics;* and that which treats of their motion, *dynamics.* So when fluids, instead of solids, are the subjects of investigation, that branch which treats of their equilibrium, pressure, &c., is called *hydrostatics,* and that which treats of their motion, *hydrodynamics.*

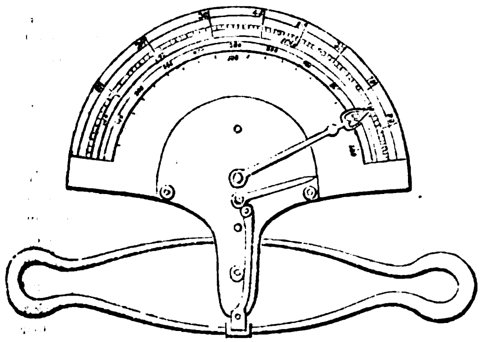
DYNANOMETER; an instrument for ascertaining the relative muscular strength of men and other animals. That it would be desirable to know our relative strengths at different periods of life, and in different states of health, will hardly be denied; and there can be no doubt but that it would be highly useful to have a portable instrument by which we could ascertain the strength of horses or oxen intended for the plough or the waggon. Such an instrument was invented many years ago, by Graham, and improved by Desaguliers; but, being constructed roughly of wood, it was too bulky to be portable, and therefore it was limited in its use.

M. Leroy constructed a much more convenient dynanometer than Graham's, consisting of a metal tube, ten or twelve inches in length, placed vertically

on a foot like that of a candlestick, and containing in the inside a spiral spring, having above it a graduated shank terminating in a globe. The shank, together with the spring, sunk into the tube in proportion to the weight acting upon it, and thus indicated, in degrees, the strength of the person who pressed on the ball with his hand.

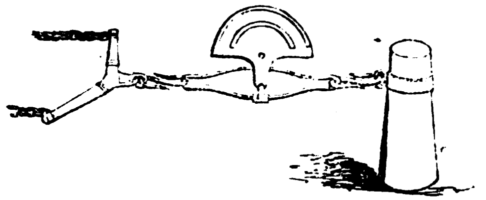
This was a very simple construction; but Buffon and Gueneau, being anxious to estimate the muscular force of each limb separately, and of all the parts of the body, they employed M. Regnier to contrive a new dynanometer; and the account which he gives of his attempts to fulfil their wishes, is calculated to enhance the difficulty of the attempt. The instrument, however, which he constructed is not of such a character as appears to have required any uncommon skill in mechanics, or any great stretch of thought. It consists chiefly of an elliptical spring, twelve inches in length, rather narrow, and covered with leather, that it may not hurt the fingers when compressed by the hands. This spring is composed of the best steel well welded and tempered, and afterwards subjected to a stronger effort than is likely to be ever applied to it either by men or animals, that it may not lose any of its elasticity by use.

The effects of this machine are easily explained. If a person compresses the spring with his hands, or draws it out lengthwise, by pulling the two extremities in contrary directions, the sides of the spring approach towards each other; and it has an apparatus appended to it, consisting of an index and a simicircular plate, by the degree of approach, and consequently of effort, employed, is ascertained with great accuracy. There is a very full account of this machine in the fourth number of the *Philosophical Magazine*.



In the above engraving we give a view of a very useful dynanometer, very similar to that already referred to. The divided arc is attached to the upper portion of the spring, and the index hand is put in motion directly the two plates approach each other, by the short perpendicular rod shown in the figure.

The engraving in the next column shows the apparatus as it is employed for measuring the strength of animals. A strong pillar is inserted in the ground, to which one end of the dynanometer is attached, and the horses or other animals hooked to the other: and it will be obvious that the efforts of the animal will be duly indicated by the hand traversing the arc. There is, however, a still more advantageous mode of employing it, which consists in attaching it to a loaded vehicle, and then the experimentalist has all the advantages which arise from employing the animal's strength in a natural way.



Dyscophosis; a defect in the sense of hearing.

Dyscracy; an undue mixture of elements in the blood or nervous juice.

Dysorexy, among physicians, denotes a want of appetite, proceeding from a diseased state of the stomach.

Dyspepsia; difficulty of digestion. The strict etymology of the term implies an imperfect or disordered condition of the function of digestion. Systematic writers have been not a little perplexed to find an appropriate location for this affection in their artificial arrangements; and this difficulty must exist whilst symptoms, which are always fluctuating, are admitted, as the elements of nomenclature and arrangement, into systems of nosology. From the same circumstance, different symptoms of the affection have received the character of separate diseases, as apepsia, bradypepsia (βραδυς, slow), anorexia, cardialgia, &c. These are no more than different grades in the symptoms, or varieties of the affection, and are not different diseases.

The disorder of the digestive function is the most frequent and prevailing of the ailments that afflict man in the civilized state; all classes and all ages suffer from its attacks. Few are so happy as to pass through a life of ordinary duration, without undergoing a protracted struggle with this malady, and experiencing its torments. Once let it be fully established, and the comfort of existence disappears, or is regained, in most cases, tediously, and at the price of the most ascetic self-denial.

The greater prevalence of dyspepsia or indigestion, in modern times, arises from the more frequent injury done to the stomach and its functions, directly, by the habits of luxurious indulgence, which have been exceedingly increased and extended; and, indirectly, by the multiplication of intellectual and moral agitations, from the extension of the commercial and financial operations of society, the greater activity and employment of the intellectual faculties, and augmentation of political, social, and individual reverses. Something, too, is to be ascribed to the mere change of names.

We call that *dyspepsia* now, which, formerly, was termed *liver disease, bilious disorder*, &c. A large proportion of the discomfort produced by this malady, arises from an ignorance of the digestive functions, leading to their abuse and premature derangement, and may be obviated, to a great extent, by instruction as to the nature of these functions, and their natural exercise. A general view of the digestive organs and functions is, therefore, requisite to an understanding of their disorders, the means to prevent, and the methods to remedy them.

All organized or animated beings hold their existence under the condition of renewing, incessantly,

the elements of their composition, by the appropriation to themselves of exterior matters. The simple animals (polypi, &c.) find, in the medium in which they live, and from which they directly receive them, the principles serving for their composition. The decomposition of animal and vegetable matter in the soil, prepares the aliment or nutritive principle of vegetables, which, being held in solution by water, is absorbed by their roots. In all these beings there are no digestive organs or functions. The preparation of their nutriment is effected by physical operations exterior to themselves, over which they have no controul. In the higher or complete animals, or in man, the case is very different. Nature does not present to them the nutritive elements in a state fitted to be introduced, at once, into the interior organization, and to be employed in its composition. Their aliment consists of the nutritive principles in a compound state, intimately combined with other substances, from which they require to be disengaged. This is accomplished by the animal itself, which is provided with especial organs, or apparatus and functions for this purpose.

Digestion, then, consists in the disengagement of the nutritive elements from their combinations, and their reduction to the molecular state, admitting their introduction into the vessels, and their diffusion throughout the organization, for the purposes of its composition. It is a process analogous to the decomposition of the aliment of vegetables in the soil, and is effected, like all decompositions, by analogous or chemical operations. In this class, the procuring of the aliment is the act of the animal, depending on its voluntary powers, and is controlled by a great variety of circumstances, affecting the quantity and quality of the food. The organs composing the digestive apparatus in man are numerous. They are the mouth, armed with teeth, for mechanically breaking down the food by mastication; the salivary glands, furnishing a fluid intimately combined with the food, in mastication, and collected in the stomach, which is its reservoir; the pharynx, a muscular and membranous bag, for the reception of the masticated food from the mouth; the œsophagus, a muscular and membranous tube, for conducting the food into the stomach; the stomach, a muscular and membranous bag, or enlargement of the alimentary canal, secreting a fluid or fluids, and reservoir of the salivary and other secretory fluids of the interior surfaces, and in which the food is subjected to the decomposing process, until reduced to a pulpy mass, called *chyme*, consisting of the nutritive and innutritive elements, in a state of mechanical mixture; the duodenum, or second stomach, in which the chymous mass is submitted to the action of the biliary and pancreatic fluids, and in which the nutritive elements begin to separate from the innutritive matters, and to be absorbed by the lacteals, the roots of the animal economy; the liver and pancreas, furnishing bile and a species of saliva, which are mixed with, and act on, the chyme in the duodenum; the jejunum and ileum, or small intestines, in the course of which the separation, begun in the duodenum, is completed, and nearly the whole of the nutritive principles forming chyle are absorbed; and, lastly, the large intestines, a reservoir for all the excrementitious principles, and which, in it, are converted into fæces. The whole of these organs compose the apparatus of digestion, but all are not of equal importance.

The stomach and duodenum are the most eminent organs, and those whose condition exercises the greatest influence over the powers of digestion. This apparatus is intimately connected, and a natural state of each of its parts, and a due exercise of the function of each, are essential to the healthy, undisturbed performance of digestion. This connection is maintained through the ganglionary system of nerves, which not only unites these organs together, but combines them with all their congeries, appropriated to the perfect elaboration of the nutritive and sustaining principles of the economy.

The stomach is the centre of the digestive apparatus, and may be regarded in nearly the same view, for the whole of the organs are connected with individual nutrition. It owes this character to its intimate union with the great solar plexus, the centre or brain, if it may be so termed, of the ganglionary system, regulating the nutritive functions. It is also immediately associated with the brain, through the medium of the eighth pair, or pneumo-gastric nerves, and thus is placed in relation with the exercise of the moral and intellectual faculties. The stomach is consequently exposed to be disordered in its functions by violent impressions from these faculties, as they are also liable to be affected by the disordered conditions of the stomach. It is necessary to have these diversified connections pointed out, to possess a clear understanding of the numerous and very different sources from which disturbances reach the process of digestion.

A few words will now be necessary as to digestion itself. It is not all substances that are fitted for aliment, and are susceptible of digestion. Food is intended for the renovation of the body. It must consist of the same elements as the animal structure, and be capable of becoming organized and living. It must then contain, at least, three elementary animal principles—hydrogen, carbon, and oxygen; and much of it contains, also, a fourth—azote. These elements form secondary compounds, in which state alone they constitute aliment: such are albumen, fibrin, gelatin, osmazome, oil, engan, farina, mucilage, and other animal and vegetable compounds. In all these substances, the molecules are easily separable without being chemically decomposed, which is one of the primary requisites of digestibility, and to effect which is the chief object of digestion. The masticated and insalivated food passes into the stomach. Here it is macerated in the saliva collected in the stomach, and in the proper liquid secreted by the villi of the gastric mucous membrane, at a temperature of 104° Fahr. This liquor is called *gastric juice*. Its true nature is not accurately determined, but, as far as examination has ascertained, it resembles saliva mixed with a small portion of lactic or muriatic acid. The stomach, in a healthy state, always contracts on its contents, so that its parietes, in digestion, are always in contact with the food. During digestion, the stomach has a constant vermicular motion, its muscular fibres contracting, successively, from the smaller to the larger end. The food is thus agitated, acquires a rotatory movement, and is mingled with the fluids of the stomach. In a short time, the change accomplished in the stomach commences; it becomes pulpy, and then reduced to a semi-fluid of a light, grayish colour. From the uniform pressure of the stomach, the solid and most resisting portions are forced into the centre, while the digested and more fluid matter is found on the surface, and is gradually carried, by the contraction

of the muscular fibres, into the duodenun. W. Phillip, and others, have been led to suppose, from this circumstance, that the food in contact with the parietes of the stomach was alone digested; but it is a mere physical result, as uniform pressure in every direction, on a mass of different consistency, will always drive the most fluid to the circumference.

The pulpy, grayish substance resulting from the stomachic digestion, is called *chyme*. When examined with the microscope, it is found to consist of an immense number of transparent globules, of various sizes, intermixed with undissolved fragments of the fibres of the alimentary substance. When food is masticated, and macerated for a few hours in simple saliva, it is found to present exactly the same appearances as the chyme of the stomach. The chyme, having passed into the duodenum, meets with the pancreatic liquor and the bile. What are the positive changes induced by these fluids, certainly is not accurately known. The acids of the chymous mass are neutralized by the alkaline principles of the bile, the picromel and colouring matter of which appear to coalesce with the unassimilable principles of the food, and assist in their conversion into fæces. A chemical modification, in some of the alimentary elements, may also be effected. It is certain that chyle, or the nutritive principles of which blood is formed, does not appear in the lacteals until after the action of the bile and pancreatic fluid on the chyme, the product of the stomachic digestion.

The action of the stomach on the food is that usually designated as *digestion*, and it is the derangement of this process that is usually expressed by the term *dyspepsia*. The process accomplished in the duodenum is also a true digestion, and the symptoms rising from its disordered state are confounded with those of the stomachic digestion, in the general accounts of dyspepsia. From this sketch of the function of digestion, it is evident, that its most important agents are, 1st, the secreted fluids collected in the stomach; 2d, the contractile movements of the stomach, keeping the alimentary mass in constant agitation, mixing it with the fluids as they are secreted, and removing the portion digested or reduced into chyme; 3rd, the application of the biliary and pancreatic fluids to the chyme in the duodenum; and, 4th, the contractile movements of this viscus.

Most of the derangements of the digestive functions may be traced immediately to a departure from a natural state of some one or more of the above requisites of digestion. But this deviation from the natural order is, itself, an effect. The secretions are products of organs, and all excitement of the secretory organ, beyond the range of healthy action, causes vitiation of the secretion, or its total suspension. The action of the organ, diminished below the physiological range, is attended with other vitiations of the fluid, or the cessation of its secretion. Indigestion, or dyspepsia, is a consequence of both these conditions of the organs furnishing the fluids of digestion. Digestion is a very stimulating process. All functional actions are exciting. The increased demand for secreted fluids renders an augmented action and increase of blood in the furnishing organ, necessary for their production. The presence of the food, drinks, &c., in the stomach, add to the stimulation of digestion. If the stomach of an animal be examined in the act of digestion, the mucous membrane is found of a diffused scarlet colour. The movements of the stomach, essential to digestion, depend on its nervous communications, and especially on the integrity of the eighth pair of nerves. When these are divided, the stomach and œsophagus are paralyzed; the food is no longer agitated and mixed up with the digestive fluids, and it often regurgitates from the stomach into the œsophagus. This experiment proves the influence of the contractile motion of the stomach in the act of digestion. The ganglionic nerves are not less important, though their specific influence cannot as readily be determined.

But in many cases of disease of these ganglions, vomiting, eructations, pain in the gastric region, and impaired digestion, are accompanying symptoms. Through the nervous system, the function of digestion is exposed to numerous disorders from moral impressions, especially those of an agitating character. From the preceding principles, it is evident that dyspepsia or indigestion is not, properly speaking, a disease, but rather a symptom, attached to diseases of the apparatus of digestion, of very various and even opposite character. No specific treatment can, therefore, be laid down for the cure of dyspepsia, but each case requires to be managed according to its peculiar cause and nature. The organ of the digestive apparatus, the most frequently productive of dyspeptic symptoms, is the stomach, and the most usual cause of dyspepsia is its irritation and inflammation.

The stomach is more liable than any other organ to these states, from its direct exposure to so many irritating aggressions, and its intimate sympathetic communications, which make it participate in the irritations of almost every other organ. The subacute and chronic forms of gastric irritation and inflammation, the signs of which have only of late been fully appreciated, are the disorders that in seven or eight cases out of ten, are termed *dyspepsia*. Hence dyspepsia so frequently succeeds to febrile diseases, especially when treated by emetics, drastics, and the improper use of tonics and stimulants, which, although the patient escapes the fever, leave him a martyr to the chronic, disorganizing and perturbating irritations of the gastric mucous membrane. Hence, too, dyspepsia almost inevitably follows continued abuse of the digestive functions, from too highly seasoned or too abundant food, and stimulant drinks. The constant stimulation of the stomach finally becomes pathological or morbid. The simple prolongation of the functional excitement essential to digestion, continued from meal to meal, without permitting the stomach to revert to a state of repose, is sufficient to constitute a morbid state. All functions, for their perfect performance, require alternate periods of repose and activity. Incessant action irritates, inflames, and finally disorganizes the structure of the organs.

A second condition of the stomach, productive of dyspepsia, is the congestion of its mucous tissue. This may be confined to the stomach alone, succeeding to an attack of acute gastritis, or following on its protracted irritation; or it may be an attendant on a general congestion of the whole portal system involving most of the abdominal viscera. Every irritation is attended with an afflux of the circulating fluids into the structure where it is seated, proportioned to its intensity and the vascularity of the structure. This gorged state often continues after the subsidence of the irritation that provoked it, and prevents the resumption of the healthy functions.

It is a state of passive congestion, and often exists in the mucous membrane of the stomach, after attacks of inflammation or acute irritation, and embarrasses its digestive operations. In all the extensive irritations of the alimentary canal, especially when attended with fever, having a paroxysmal character, the great portal system of the abdomen becomes loaded with blood, and congestion of its radical vessels ensues. The functions of the viscera are then disordered, the secretions are defective, and indigestion, costiveness, and their attendant nervous affections, are the necessary consequences of this condition.

A third state of the stomach, a cause of dyspeptic symptoms, is precisely the reverse of the preceding. Asthenia, or diminution of vitality and actions below the healthy degree, occasionally takes possession of the stomach. Its circulation is then deficient, its secreted fluids are defective in quantity or quality, its sensibility is impaired, and digestion is imperfect. It is not probable that gastric asthenia is ever primitive. It succeeds to previous irritation, and is often occasioned by irritation in other organs.—The preceding form a first class of dyspeptic diseases, which, depending entirely on the stomach, may be termed *gastric dyspepsia*. They present characters totally different, and require a very opposite treatment. This class embraces three species.

A second class of dyspeptic diseases is connected with the duodenum and its functions. This viscus, similarly constituted to the stomach, is subject to the same morbid alterations. Its mucous membrane is the seat of irritation, in its various grades, and productive of its usual consequences—augmented irritability, sensibility, perversion of secretions, vitiation of structure, and disorder of function. Duodenic irritation most commonly accompanies gastric irritation, and the symptoms of the two are blended together. It exists, however, in many instances, independently; and then manifests particular symptoms, which are often termed *dyspepsia*. It is, more especially, the chronic irritation of the duodenum, that passes for dyspepsia.

It is not probable that congestion, or asthenia, ever affect the duodenum exclusively to the detriment of its function. When these states prevail, it is in conjunction with similar conditions of the whole digestive apparatus. At least, we have no knowledge of these states limited to the duodenum.

A third class of dyspeptic diseases depend on the nervous organs, which furnish nerves to the digestive viscera. The ganglionic system of nerves, distributed on each side of the spine, from the head to the pelvis, transmits nerves to all the organs connected with the nuritive function. The stomach, especially, is largely supplied from the solar plexus, and it receives, likewise, numerous nervous filaments from the pneumogastric, placing it in connection with the functions of relation.

The offices of the ganglionic system are not ascertained with precision. It is, however, well determined, that diseases of the ganglions disorder the functions of the viscera to which they transmit nerves. Hence arises an order of dyspeptic symptoms, independent of any immediate affection of the stomach, but occasioned by disease in the great solar, or other neighbouring plexus. The disorders of the digestive functions, from this cause, are various. The sensibility of the stomach is sometimes greatly increased, constituting gastrelgia. At other times, the secreted fluids of the stomach are morbidly acid.

The stomach appears, in other cases, to be partially paralysed, and the peristaltic movements necessary for the admixture of the food, and the gastric fluids, and the continuous passage of the chyme into the duodenum, are suspended. At the same time, considerable quantities of flatus collect in and distend the stomach, preventing its action on the food. Mechanical manipulation of the abdomen, and particularly of the epigastrium, after a meal, becomes a substitute for the natural motion of the stomach, expels the wind, and facilitates digestion, that would otherwise be laborious and painful.

Dyspepsia, or indigestion, from this analysis of its modes of production, is seen not to be a disease of uniform character, and depending on an identical state of the digestive organs. It is attached, as a symptom, rather, to a variety of conditions, each of which requires to be managed in its appropriate mode. It is not possible that it can be remedied by any one general mode of treatment, or by any set of specific remedies. The most common causes of dyspepsia are excesses of various kinds, especially in the quantity of food eaten. Most individuals, in this country, err in this respect. Meat at three meals, daily, can be borne only by the most robust frames, and by hard labourers. Persons of a sedentary life require less nutriment; the economy makes less demand on the stomach for supplies; and if it be compelled then to labour, it is at its own loss. Exercise, or the expenditure of the nutritive elements by the economy, and the quantity of food to be digested, must be proportioned to each other, for the preservation of health and the due vigour of digestion.

Good cookery, by rendering food more digestible, is one preservative against dyspepsia. The food, by being rendered tender and pulpy, is reduced to chyme in a shorter period, with a smaller expenditure of the secreted fluids, and less excitement of the stomach, than when it is not properly concocted. The art of long and healthful living will depend on a perfect system of cooking, and a rational mode of eating.

The powers of the stomach differ, in individuals, as much as the force of their muscles; and each one must adopt a mode of nutrition, both as to quantity and quality of food, suitable to the wants of his economy and the digestive capacity of his stomach. The quality of food is a frequent cause of dyspepsia. Tough and badly dressed meats, and crude vegetables, are among the prominent causes of this affliction, as are also hot bread and cakes, heavy and fresh bread, and the immoderate use of hot fluids for breakfast. In enumerating the more common causes of dyspeptic symptoms, we ought not to omit the frequent exacerbations of the malevolent passions, as anger, hatred, envy, jealousy, and, what is not often suspected, excessive indulgence and abuses of the venereal propensity Another fruitful source of the digestive disorders is found in the employment of emetics, and in a frequent resort to saline or drastic cathartic medicines. When a constipated habit prevails, it should always be overcome, if possible, by a laxative regimen, and the aids of purgatives be cautiously and rarely invoked. Above all, we may add, healthful exercise and well ventilated apartments will tend most materially towards preserving the health of those persons in whom a disposition to dyspepsia prevails.

EAR AND EYE

Dyspepsy. See preceding article.

Dysphonia; a difficulty of speaking.

Dyspnoea; a difficulty of breathing, usually called asthma, which see.

EAGLE, in *astronomy;* a constellation of the northern hemisphere, having its right wing contiguous to the equinoctial.

Eagle, in *architecture*, is a figure of that bird anciently used as an attribute of Jupiter in the capitals and friezes of the columns of temples consecrated to that god.

Ear. The mechanism of *hearing* is simple in its arrangement, and beautifully adapted to the purposes of life. Fitted in an eminent degree to the purposes it is designed to execute, the ear offers an inviting subject to such as are disposed to investigate the minute mechanism of an organ, which contributes remarkably to some of our most exquisite and refined enjoyments. Whoever has witnessed and attentively observed the distressing effects arising from a loss, or diminution of its sensibility, will readily acknowledge that such deprivation throws us at a distance from our fellow-creatures, and, in the present state of society, renders us more solitary beings than the loss of sight itself. Though the rapid glance of the eye, the immense distance to which it enables us to carry our perceptions, and the extended circle it embraces, have given rise to some of our most pleasurable and refined sensations; though it has brought us acquainted with objects which seemed ever placed far beyond our reach; still, the more humble sense which we are now considering, the more confined dominion of the ear, has contributed most efficiently to the every-day happiness of life. It enables us to hold communication with our fellow-creatures; to improve and exalt our understandings by the mutual interchange of ideas; and thus to increase the circle, not only of our physical, but of our moral relations. The charms of eloquence, the pleasure resulting from the concord of sweet sounds, inexplicable perhaps as it remains, are other sources of intellectual enjoyment, which contribute to place this sense among the most delightful as well as the most important we possess. Whatever, therefore, by explaining its structure, or examining its functions, can lead us to improve its natural, or restore its disordered sensibility, cannot be a subject of trivial moment. Our more immediate object is to consider the human ear, observing only, that the structure of the organ, being suited to one great end, is in all cases fundamentally the same; its different forms and varieties depending on the peculiar economy and abode of each individual creature.

The organ of hearing, in its simplest form, consists of the expansion of a nerve, gifted with peculiar sensitive qualities, over the surface of a delicate membrane. In man and the more perfect animals, there is an additional apparatus connected with this, the design of which is supposed to be that of collecting and modifying those pulses of sound which are finally to be impressed on the nervous pulp. In man this apparatus consists of a piece of cartilage, seated externally to the head, which contracts into a funnel leading to the internal parts. The bottom of this tube is truncated obliquely, and its aperture closed by a firm membrane stretched across it, which separates this external part of the ear from the succeeding, or middle portion of the organ. Beyond, or on the opposite side of this membrane, we meet with a small cavity, hollowed out in bone, which has been termed the barrel of the tympanum. Of the several openings into it, there is one more particularly demanding our attention here. It is the internal aperture of a tube, the other extremity of which opens at the posterior part of the nose, behind and above the palate. By means of this communication, the external air is admitted into the chamber, and equipoises the weight of the atmosphere on the other side of the membrane. Across the cavity there is extended, though by no means in a straight line, a series of little bones, the exterior one of which is attached to the membrane we have just mentioned, the most internal of the set being firmly connected with another membrane, which, in conjunction with it, shuts up the entrance to a still more deepened cavity, called the labyrinth of the ear. This last hollow, excavated as it were in the solid bone, consists of a middle portion of irregular figure, and of different channels, which proceed from it in various directions, and, finally, return, with the exception of one only, to the same chamber. All these passages are lined by a membrane, on which the sentient extremity of the auditory nerve is expanded in different shapes; from these it is collected into one trunk, and goes on to join a particular part of the brain, and thus completes the communication between the external agent and the sensorium.

The anatomy of the external ear may, however, be best understood by referring to the illustrative engraving, *figure* 1, plate of the *Ear* and *Eye*.

The meatus externus is seen detached from the bone at *b*. The oblique direction of its internal end is shown at *d e*, the membrana tympani stretched on its bony ring, and bulging inwards.

f g h, the malleus: *f*, the handle or process attached to the membrana tympani; *g*, the long process; *h*, the head.

i k, the incus: *i*, the short leg or process; *k*, the long process.

m, the stapes.

V H A, the curved labyrinth: *n p*, the cochlea; *n*, its beginning, its termination at *p*; this is followed by the vestibule; V, the bony case of the anterior, or smaller of the semicircular canals; H, the posterior, or largest semicircular canal; A, the outer, or smallest canal.

The external part of the ear is differently formed in different animals; and admirably suited to their various situations and habits. In man, it is close to the head, but so formed as to collect the various pulses with great accuracy; in other animals it is more simple, where less accuracy is required, but it is in general much larger, having the appearance of an oblong funnel; and this gives them a greater delicacy of hearing, which was necessary for them.

Dr. Savart considers the external ear as an important auxiliary to the tympanum, capable also of entering into vibration by communication, and having for its principal function to present always to the air (by the various directions and inclinations of its surfaces to one another) a certain number of parts, upon which the undulations of the air shall fall perpendicularly. The little muscles which are inserted in it, he thinks, contribute by their action to increase its tension, and render it more elastic.

Within the cavity of the tympanum are placed four

small bones, which facilitate the hearing: the first is the malleus, or hammer, so called from its shape: the upper part of its round head rests upon the concavity of the tympanum, from whence the handle is extended down, along the membrane of the tympanum. This bone has several muscles, which move it in different directions, and cause it to stretch, or brace the membrana tympani, when we wish to hear with accuracy.

Connected with the malleus is another small bone called the incus, or anvil, which is connected with another called the stapes, or stirrup, from its shape. These two bones are connected by a small oval-shaped bone called os orbiculare, placed between them: the whole forming a little chain of bones.

The stapes, or stirrup, has its end of an oval form, which fits a small hole called fenestra ovalis, in that part of the ear called the labyrinth, or innermost chamber of the ear.

The labyrinth consists of three parts: first, the vestibule, which is a round cavity in a hard part of the os petrosum; secondly, the semicircular canals, so called from their shape, which, however, is not exactly semicircular; thirdly, the cochlea, which is a beautifully convoluted canal, like the shell of a snail. This part has a round cavity called fenestra rotunda, which is covered with a thin elastic membrane, and looks into the tympanum.

The vestible, semicircular canals, and cochlea, the whole of which is called the labyrinth, form one cavity, which is filled with a very limpid fluid resembling water, and the whole lined with a fine delicate membrane, upon which the auditory nerve is expanded, like the retina upon the vitreous humour of the eye. This beautiful apparatus was lately discovered by an Italian physician, Scarpa. The auditory nerve is a portion of the seventh pair, which is called the portio mollis, or soft portion.

There is one part of the ear still to be described; namely, the Eustachian tube, so called from Eustachius, the anatomist, who first described it.

This tube opens by a wide elliptical aperture into the tympanum behind the membrane; the other end, which gradually grows wider, opens into the cavity of the mouth. By this canal the inspired air enters the tympanum to be changed and renewed; it likewise serves some important purpose in hearing, with the nature of which we are yet unacquainted. It is certain that we can hear through this passage, for if a watch be put into the mouth, and the ears stopped, its ticking may be distinctly heard; and in several instances of deafness this tube has been found completely blocked up. Though the use of the Eustachian tube has been doubted, as conveying sound by the mouth, yet a simple experiment will convince us, that it has some influence in this respect; thus, if a deaf person is to converse with another, and a wire or other medium of communication is made to pass to the mouth of each, by placing its extremity between the teeth, the deaf person will hear the conversation better than without this assistance, which certainly proves, that part of the vibrations of sound is carried along the wire into the mouth, and applied to the ear through the Eustachian tube in the throat; while a part also reaches the ear externally, and is collected in the auricle in the usual manner. We have seen people quite deaf to outward sounds, enjoy a concert on the piano-forte, by means of a long narrow bar of wood placed on the instrument, the opposite end being grasped between the teeth.

We have now to notice the labours of M. Savart, who has paid considerable attention to the anatomy and uses of the tympanum.

By a series of experiments, which, fortunately for the cause of humanity, have not been verified in this country, he ascertained that the membrane of the tympanum exactly resembled in its effects the vibrations of a drum, or plate. (See Acoustics.)

That the membrane of the tympanum may justly be compared with an ordinary membrane acted upon by communicated vibrations. This was proved, by submitting the real ear to the following experiment:—after having removed the temporal bone, he made with the saw a section parallel to the external surface of the membrane, so as to lay it open, and to be enabled to cover it with sand: the sand was observed to be slightly put in motion, when a vibrating plate was brought parallel with the membrane, and very near its surface; but it was impossible, from its limited extent, and particularly on account of its form, to prove the existence of any distinct nodal line. The existence of the motions was rendered much more evident, by substituting for the human tympanum the drum of a calf's ear.

He observed, also, that when the internal muscle of the malleous acted, and, consequently, that when the membrane was tightened, it was more difficult to produce evident motions in the grains of sand; so that the uses of this little muscle appear, like those of the iris, to consist in preserving the organ from impressions too intense, which, under certain circumstances, it might otherwise receive.

The membrane of the tympanum may be considered as a body put in motion by the air, and performing always a number of vibrations equal to that of the body which has produced the oscillations in the air; but, besides, as the direction of the molecular motions of the membranes, and generally of all bodies, continually vary with the direction of the vibrations of the body directly put in motion, it may be presumed that it is by this means that we are able to judge of the direction of the sound, when it arrives without having been reflected.

The following experiment shows, that if the auditory passage, the concha, and the bell of the ear, serve to render the aerial oscillations more intense, they also are of use to reciprocate the vibrations of the air, and to transmit them to the membrane of the tympanum, with the same degree of force, whatever may be their direction. A very wide conical tube was formed of thin pasteboard, and to its smaller end a thin and tended membrane was firmly fastened: on bringing in a parallel direction to the upper and external surface of this membrane, when covered with sand, a vibrating plate, the grains of sand were but slightly put in motion; but on placing the plate near the large orifice of the tube, they became strongly agitated. Another conical tube was opposed by its summit to the preceding, but without touching the membrane, and afterwards the plate was put in vibration at the larger orifice of each of the tubes: it was observed that the communicated motions were incomparably more energetic when the aerial undulations arrived through the tube which was in immediate contact with the membrane, than when they arrived through that which did not touch it.

Another experiment shows the important influence

which the malleus, fastened upon the internal surface of the membrane of the tympanum, exercises upon the nature of its motions. If a small wooden rod, reduced at its edges, be fixed on a stretched membrane, so that it may extend itself from the centre to the circumference, or even beyond, the figures produced by the membrane will be modified by the presence of the little rod, and the latter will be caused to vibrate so strongly, that very distinct nodal lines will be produced in it, even when its dimensions are rather considerable.

It appears then from this, that the malleus fulfils at the same time two distinct functions: first, it modifies, by means of its muscles, the tension of the membrane, in order to preserve the organ from over-intense impressions, and to dispose it conveniently to receive the weakest impressions; and, secondly, it reciprocates the motions of the membrane, and communicates them to other parts. Since this bone is in immediate contact with the incus, and the incus communicates with the lenticular bone, and, by its means, with the stapes, it is evident that the membrane of the tympanum cannot vibrate, without producing corresponding oscillations in the membranes of the fenestra ovalis. The mechanism which causes the tension of the latter membrane, and preserves the soft parts contained in the labyrinth from intense impressions, may be illustrated by an experiment. Had the membranes which close the entrances of the labyrinth been in immediate contact with the atmospheric air, their elastic state would have been continually influenced by the changes of temperature of that fluid. It may, therefore, be presumed, that the use of the membrane of the tympanum is to prevent the direct contact of the atmospheric air, and that the case of the drum and the mustoid cells form a kind of receptacle, in which the air, already warmed, coming from the mouth through the Eustachian tube, acquires the constant temperature of the body, in order to establish, before the apertures of the labyrinth, an atmosphere, the properties of which are invariable: so that it is probable that the great temporal artery, separated from the case of the drum only by a very thin bony partition, is of some importance in the mechanism of audition.

In *deafness*, the auditory nerve first fails to detect the soft distinctions of sound; vibrations must be stronger and stronger, to convey through the medium of a thickened tympanum, impressions to the brain. But while the faculty of hearing declines, the nerves may be occasionally so much excited, that they will detect sounds with their wonted acuteness. A very striking instance of this is apparent in the case of a gentleman, so deaf that he could only hear the voice when raised to its highest pitch, and yet, when riding in a carriage rattling along the streets, he could hear common conversation without difficulty. It would, by this, appear, that the powers of hearing, although impaired, yet being greatly excited by this discordant din, and the tympanum or drum of the ear placed in more than ordinary tension, the sense was partially restored.

Dr. Wollaston discovered the very singular fact, that there were persons who never felt any defect in their hearing, and who yet could not hear certain sounds, which others perceive distinctly.

It is well known, that persons affected with slight deafness, hear sharp sounds much better than those which are grave and low. They distinguish the voices of women and children, from their acuteness, much better than the lower tones of men's voices. This fact is acted upon practically, as it may be remarked, that those accustomed to speak to deaf people use a shriller tone of voice, rather than merely a louder tone than common.

This partial deafness may be artificially produced, by shutting the mouth and nose, and exhausting the air in the Eustachian tube, by a forcible attempt to take breath by expanding the chest. When this is carefully done, so that the exhaustion of the air behind the drum of the ear is as complete as possible, the external air is felt strongly, and even painfully, pressing on the drum; and the ear becomes insensible to low sounds, though shrill sounds are as readily perceived as before.

After the ear is brought into this state, it will remain so for some time, without continuing the painful effort to take breath, and even without stopping the breath; for, by suddenly discontinuing the effort, the end of the tube will close like a valve, and prevent the air from getting into the drum. The act of swallowing will open the closed tube, and restore the ear to its wonted feeling.

When the ear is thus exhausted, if we attempt to listen to the sound of a carriage passing in the street, the rumbling noise cannot be heard, though the rattle of a chain or loose screw remains as easily heard as before. At a concert the experiment has a singular effect: as none of the sharper sounds are lost, and the great mass of the louder sounds are suppressed, the shriller ones are consequently so much the more distinctly heard, even to the rattling of the keys of a bad instrument, or the scraping of catgut unskilfully touched.

On examining the external ear in *quadrupeds*, it is found to resemble the oblique section of a cone, from near the apex to the base. Hares, and other animals exposed to danger, and liable to be attacked by men, or beasts of prey, have large ears, and they are particularly directed backwards; while their eyes at the same time, full and prominent, warn them of any danger in front. Rapacious animals, on the contrary, have their ears placed directly forwards, as is observable in the lion, the tiger, the cat, and others.

All animals, as far as we know, possess the sense of hearing: it was formerly doubted with respect to fishes.

The organ of hearing in fishes was first discovered by the late Mr. John Hunter; and is prosecuted at a considerable length, in his work on the organ of hearing in fishes, by the late Professor Monro, of Edinburgh. Thus the modern researches and discoveries in comparative anatomy have sufficiently established their possession of this sense, as well as the other classes.

In cray-fish, and the sepiæ, the organ is most simple, consisting of a small cavity or vestibule, and a single membranous tube. The spinous fishes, in addition to the hollow of the vestibule, and membranous bag containing the lappilli, are provided with semicircular canals; whilst, in the osseous fishes, the whole is enclosed by bone. To the labyrinth of the serpent tribe, which is very similar to the internal ear of the cartilaginous fishes, there is added an officulum, closing the fenestra ovalis. In one of this order, and in almost all the four-footed reptiles, the membrana tympani is furnished with this officulum.

In prosecuting our inquiries farther, the ear has

been discovered in insects; it lies at the root of their antennæ, or feelers, and can be distinctly seen in the lobster, and some others of the larger kind.

In the sea-tortoise, the frog, and other amphibious animals, its structure is peculiar, by there being no external meatus, but an expanded Eustachian tube, at the back part of the roof of the mouth, near where the under and upper jaws articulate. This tube has a winding course behind the upper jaw, and leads to a large cavity, resembling the cavity of the human tympanum, covered by the skin of the temple and a tough substance. The latter then passes into the bottom of the tympanum, and next into a smaller cavity filled with a watery humour, and last it opens into a third cavity, having three semicircular canals, and a sac containing a soft cetaceous substance, on the membrane of which are distributed the nerves. Thus, making a comparison of it with the human ear, the tough substance, or cartilaginous body, supplies the place of the small bones of our ear, and the membrane to which it is connected is analogous to the membrane of the foramen ovale. The sac, and semicircular canals and nerves, exactly resemble the human labyrinth, or internal ear.

Ear-trumpet. The mode of constructing a *trumpet* for the purpose of conveying sounds to a distance was well known to the ancients. Its invention is, however, usually ascribed to Sir Samuel Morland, who called it the *tuba Stentorophonica.* An account of this instrument was published at London in 1671, in which the author relates several of his early experiments; the result of which was, that a speaking-trumpet constructed by him, five feet six inches long, twenty-one inches diameter at the greater end, and two inches at the smaller, being tried at Deal Castle, was heard at the distance of three miles, the wind blowing from the shore. Kircher, in his *Phonurgia Nova,* published in 1673, says, that "the tromba, published last year in England, he invented twenty-four years before, and published in his *Misurgia*:" he adds, that "Jac. Albanus Ghibbisius and Fr. Eschinardus ascribe it to him; and that G. Scottus testifies of him that he had such an instrument in his chamber in the Roman college, with which he could call to, and receive answers from, the porter.

In a speaking-trumpet, the sound in one direction is usually supposed to be increased, rather by the reflection of the sound than by its greater intensity in one direction; and as the real action of the instrument, or the true motion of the air through it, is not generally understood, different persons, according to their particular conceptions of the case, have recommended peculiar shapes for the construction of such trumpets: some suggest a conical shape; others, that which is formed by the rotation of certain curves round their axis; others, again, have recommended an enlargement or two of the cavity in the length of the trumpet; but that which has been most commonly recommended, as the best figure for such a trumpet, is generated by the rotation of a parabola about a line parallel to the axis.

The true physical explication of the speaking-trumpet appears to have been first given by Professor Leslie. "In the case of articulate sounds," says he, "the confining of the air does not affect the pitch of voice, but it augments the degree of intonation. The lateral flow being checked, that fugacious medium receives a more condensed and vigorous impulsion. As the breath then escapes more slowly from the mouth, it waits and bears a fuller stroke from the organs of speech. But the speaking-trumpet is only an extension of the same principle; its performance does certainly not depend upon any supposed repercussion of sound; repeated echoes might divide, but could not augment the quantity of impulse. In reality, however, neither the shape of the instrument, nor the kind of material of which it is made, seems to be of much consequence. Nor can we admit that the speaking-trumpet possesses any peculiar power of collecting sound in one direction, for it is audible distinctly on all sides.

To put the construction of this instrument in the plainest and simplest point of view, we have only to suppose the lips to be enclosed at A, *Fig.* 2, Plate of the *Ear* and *Eye*, and, as such, that the aerial pulse is directed parallel to the axis of the tube. If this system of enclosure were not resorted to, the air would expand itself in every direction, instead of being propelled in the required line; but, the instant the wave spreads, it is received by the reflecting surface B, from whence it impinges at C, and thence, by repeated reflection, to D, E, and F. The direction it has now acquired will be indicated by the lines F H, which are parallel to the axis of the tube, so that by this method a concentration of sound takes place, which could not be effected by any other means.

The *ear-trumpet* differs but little from the acoustical apparatus just described, as a reference to the diagram *Fig.* 3, Plate of the *Ear* and *Eye*, in which two trumpets are seen placed opposite to each other, will readily show. In the one case, the lines show the way in which the aerial pulses are propelled from the lips in any required direction; while, in the other, they are collected, and received by the organs of hearing.

Mr. Gough has tried several experiments on ear-trumpets, which are very deserving of notice: the first experiments were made with a view to determine the degree in which hearing was assisted by the vibrations excited in the metallic shell of the trumpet, and conveyed by it to the orifice of the auditory duct. The result of these experiments was, that absolute contact of the thing producing the sound, with the apparatus for the ear, was necessary, in order that the latter should produce its effects. The ticking of a watch, the scratching of a pin, or even that of a twisted piece of paper, was conveyed well by the instrument, when in contact with it (every other avenue for sound being carefully prevented), but the sound was no longer heard when the watch was moved the smallest distance from the instrument, or when the other noises were made in similar circumstances.

Earth. The form and motions of the planet on which we live, and on which is concentrated so many of our enjoyments, will be examined in this article. That it is a "fair and beautiful earth to look upon" must be admitted by every unprejudiced person, and it has, as far as we have any means of judging by our own feelings, many advantages over the other planetary bodies.

To an observer who possesses an unobstructed view, the earth presents the appearance of a circular plain, on the circumference of which the heavens appear to rest. Accordingly, in remote antiquity, the earth was regarded as a flat, circular body, floating on the wa-

ter. But the great distances which men were able to travel soon refuted this limited idea as an optical illusion; and, even in antiquity, the spherical form of the earth began to be suspected. On this supposition alone can all the phenomena relating to it be explained. A sphere of such great magnitude as our earth, surrounded by a stratum of air, or the visible firmament, must present to the eye of an observer on a plain, the appearance just described.—But how could the earth appear, from every possible position, as a surface bounded by the firmament, if it were not a sphere encircled by it? How else could the horizon grow wider and wider, the higher the position we choose? How else can the fact be explained, that we see the tops of towers and of mountains, at a distance, before the bases become visible? But, besides these proofs of the sphericity of the earth, there are many others, such as its circular shadow on the moon during an eclipse, the gradual appearance and disappearance of the sun, the inequality of day and night, the changes in the position and course of the stars, and the gradual disappearance of some and appearance of others, as we go from the equator to the poles. Finally, if the earth were not spherical, it would be impossible to sail round it, which is frequently done. The cause of the earth's sphericity is very evident, if we consider it as having been, at first, a yielding mass, capable of assuming any form: then, by the force of gravity, every particle contained in it tending towards the common centre, the globular form is the necessary consequence. The earth is not, however, an exact sphere, but is flattened at the poles. Philosophers were first led to observe this by the variations in the vibrations of the pendulum, under the equator, and near the poles.

It was found that the pendulum performed its vibrations slower, the nearer it approached the equator, and hence was inferred the variableness of the force of gravity. This was easily explained on the theory just mentioned, because, the circle of daily revolution being greatest at the equator, all bodies revolve proportionally faster there than at the poles, so that the centrifugal force is greater, and the force of gravity less, than at other parts of the earth's surface; and because at the equator, the centrifugal force is exactly opposed to that of gravity, but towards the poles, being oblique to it, produces less effect. From these observations it was justly inferred, that the earth is a sphere, flattened at the poles, or a spheroid; and this form was satisfactorily accounted for by the fact that the particles of a yielding mass, which revolves on its own axis, depart from the poles and tend to the centre, by which the poles are, of course, flattened, and the middle elevated. Various measurements have put this beyond all doubt. (See Degree, Measurement of.)

Another important desideratum for a more intimate acquaintance with the earth was, to fix its magnitude. The labours of the ancients, in this respect, were all fruitless, owing to their want of suitable instruments. Accurate results were first obtained in the year 1615, Willibord Snellius, a Dutchman, first struck into the true way, and measured an arc of a meridian from Alcmaar to Leyden and Bergen op Zoom, by means of triangles. After him, the measurements of Picard, and the later ones of Maupertuis, approximated nearer the truth. These made the circumference of a great circle of the earth 25,000 miles. But it is to be remarked that, in this calculation, the earth is regarded as a perfect sphere. Farther measurements of all parts of the surface of the earth will be necessary, to find rigidly and accurately, the true magnitude of it.

If we take a view of our earth in its relation to the solar system, astronomy teaches us that, contrary to appearances, which make the sun revolve about the earth, the earth and ten other planets revolve about the sun, and, being themselves opaque bodies, receive from the sun light and heat.

The earth completes its revolution round the sun in about 365 days and 6 hours, which forms our common year. The orbit of the earth is an ellipse, with the sun in one of its foci. Hence the earth is not equally distant from the sun in all parts of the year: its least distance is estimated at 93,336,000 miles, and its greatest, at 95,484,572, making a difference of more than 2,000,000 of miles.

In winter, we are nearest the sun, and in summer, farthest from it; for the difference in the seasons is not occasioned by the greater or less distance of the earth from the sun, but by the more or less oblique direction of the sun's rays. The length of the path travelled over by the earth is estimated at 567,019,740 miles, and, as this immense distance is passed over in a year, the earth must move 17 miles a second—a rapidity so far exceeding our conceptions, that it gave very just occasion to the pleasant remark of Lichtenberg, that, while one man salutes another man in the street, he goes many miles bareheaded without catching cold. Besides this annual motion about the sun, the earth has also a daily motion about its own axis (according to mean time, in 23 hours, 56 minutes and 4 seconds). This diurnal revolution is the occasion of the alternation of day and night. But as the axis on which the earth performs its diurnal rotation forms, with its path about the sun, an angle of 23½ degrees, the sun ascends, from March 21 to June 21, about 23½ degrees above the equator towards the north pole, and descends again towards the equator from June 21 to September 23; it then sinks till December 21, about 23½ degrees below the equator, towards the south pole, and returns again to the equator by March 21. This arrangement is the cause of the seasons, and the inequality of day and night attending them, which, for all countries lying beyond the equator, are equal only twice in the year, when the ecliptic coincides with the equator. The moon, again, revolves about the earth, in a similar elliptical path, in 28 days and 14 hours. Copernicus first laid down this as the system of the universe.

To the physical knowledge of the earth belongs, especially, the consideration of its surface and its interior. The earth's surface contains above 196,000,000 square miles, of which scarcely a third part is dry land; the remaining two thirds are water. Of the surface of the earth, Europe comprises about one 54th part; Asia, one 14th; Africa, a 17th; and America, a 16th. The islands of the Pacific, taken together, are somewhat larger than Europe. The population of the whole earth is estimated at from 800 to 1000 millions. The interior of the earth is entirely unknown to us, as the depth to which we have been able to penetrate is nothing in comparison with its diameter. Many modern speculators are of opinion that the interior is composed of a metallic mass. Respecting the origin and gradual formation of the earth, there are various hypotheses.

The earth has two motions, the daily motion round its axis, and the yearly motion in its orbit round the sun. The theory of the motion of the earth has become memorable in the history of the human mind, showing, as it does, a marked ability in man to resist the impressions produced by appearances, and to believe the contrary of that which had been believed and taught for many centuries.

The theory of Copernicus not only founded the modern system of astronomy, but made men eager to examine other articles of their creed, after they were thus convinced that they had erroneously taught and believed the earth to be stationary for 6000 years. All the opinions of the ancients respecting the motion of the earth were speculative hypotheses, arising from the Pythagorean school, which, as we know, considered fire the centre of the world, round which all was moving. Thus we ought to explain the passage of Aristarchus of Samos, mentioned by Aristotle in his *Arenario*. Aristarchus, as a Pythagorean, held the idea that the earth revolves round its axis, and, at the same time, in an oblique circle round the sun; and that the distance of the stars is so great, that this circle is but a point in comparison with their orbits, and therefore the motion of the earth produces no apparent motion in them. Every Pythagorean might have entertained this idea, who considered the sun or fire as the centre of the world, and who was, at the same time, so correct a thinker, and so good an astronomer, as Aristarchus of Samos. But this was not the Copernican system of the world. It was the motions of the planets, their stations, and their retrogradations, which astronomers could not explain, and which led them to the complicated motions of the epicycles, in which the planets moved in cycloids round the earth.

Aristarchus lived 280 B. C., Hipparchus, the great astronomer of antiquity, 150 B. C., therefore 130 years later. At this time, all the writings of Aristarchus were extant, and, had the Copernican system been set forth in them, Hipparchus would not have despaired of explaining the motions of the planets. The same is true of Ptolemy, in whose *Almagest*, the most complete work of antiquity on astronomy, this system is not mentioned in the account of Aristarchus. Every Copernican speaks of the motion of the earth, but not every one who speaks of the motion of the earth is a Copernican. Copernicus was led to the discovery of his system by a consideration of the complicated motion of the planets, and, in the dedication of his immortal work, *De Revolutionibus Orbium*, to pope Paul III., he says, that the truth of his system is proved by the motion of the planets, since their successive stations and retrogradations are the simple and necessary consequence of the motion of the earth round the sun; and we need not take refuge in the complicated epicycles.

Copernicus did not live to see the persecutions which the Roman Catholic priests raised against his system. They began only 100 years later (about 1610), when the telescope was invented, when the moons of Jupiter and the phases of Venus were discovered, and, by these means, the zeal for astronomy had been highly excited. Every city in Italy was then a little Athens, in which the arts and sciences flourished. Galileo obtained high distinction, and defended the new system of the world. The Roman Inquisition summoned him before its tribunal, and he was compelled to abjure this theory. (See GALILEO.) The general sympathy for the fate of this astronomer increased the popularity of the system, and it was as violently defended on one side as it was attacked on the other.

Among the arguments against the motion of the earth, it was alleged, that a stone, falling from a tower, did not fall westward of the tower, notwithstanding this had advanced eastward several hundred feet during the four or five seconds of the fall of the stone. Copernicus had answered justly: the cause of its remaining near the tower is, that it has the same motion eastward, and, in falling, does not lose this motion, but advances with the earth. Galileo said the same, and asserted that a stone, falling from the top of the mast of a vessel, at full sail, falls at the foot of the mast, notwithstanding the mast advances, perhaps 10 or more feet during the fall. Gassendi tried these experiments in the harbour of Marseilles, and the stones fell at the foot of the mast, notwithstanding the vessel was under full sail. Galileo therefore maintained, that it was impossible to draw any conclusion concerning the motion of the earth from such experiments, since bodies would fall on the earth in motion precisely the same as on the earth at rest.

In 1642, Galileo died. In the same year, Newton was born. He proved, in 1679, that the opinion of Galileo was erroneous, and that we certainly could try experiments on the motion of the earth; that the balls would not deviate westward, but would fall a little eastward of the plumb-line, about a half inch at the height of 300 feet. The cause is this: since the top of the tower is at a greater distance from the axis of the earth than its base, the centrifugal force must be greater at the former point than at the latter; the ball, in falling, does not lose this impulse, and, therefore, advances before the plumb-line, which strikes the foot of the tower, since it has a less impulse eastward. This hint, given by Newton, was followed by Hooke. He tried experiments on the motion of the earth, at a height of 160 feet, and asserts that he succeeded. The academy appointed a committee, Jan. 14, 1680, in the presence of which he was to repeat his experiments. Probably they were not satisfactory, since they have never been mentioned in the *Philosophical Transactions*, and were entirely forgotten. Only 112 years later, a young geometrician in Bologna, Guglelimini, attempted to repeat these experiments, which had been considered very difficult by astronomers, in the tower Degli Asinelli, in that city, at a height of 240 feet. After having surmounted all difficulties, he succeeded in causing the fall of 16 balls, which perceptibly deviated eastward. But Guglielmini, committed an error in not suspending the lead every day when he tried his experiments, of which he often made three or four in one night. He did not drop the plummet until after he had finished all his experiments, and as it did not come to a perpendicular position until six months, on account of stormy weather, the tower in the mean time was a little bent, the point at which the plummet should have fallen was altered, and his experiments were lost. This happened in 1792. Benzenberg, a German, performed similar experiments in 1804, in Michael's Tower, in Hamburg. He let fall 30 balls, from the height of 235 feet: the balls deviated from the perpendicular four lines eastward. But they deviated, at the same time, 1½ line south-

ward, probably owing to a gentle draught of air in the tower. He repeated these experiments in 1805, in a coalpit, at Schlebusch, in the county of Mark, at the height of 260 feet: there the balls deviated from the perpendicular five lines eastward, just as the theory of the motion of the earth requires for the latitude of 51°, but neither southward nor northward. From these experiments, Laplace calculated that the chances are 8000 to 1, that the earth turns round its axis.

The invention of the telescope, by means of which the rotation of Jupiter was soon observed, but still more Newton's discovery of universal gravity, and of the nature of the celestial motions, established the theory of the motion of the earth; and, in modern times, no man of intelligence doubts it any longer. The French General Allix, however, endeavoured to prove that the motion of the planets could not depend on the law of gravitation.

The flattening of the earth (see DEGREE, MEASUREMENT OF), and the diminution of gravity in the vicinity of the equator, proved by the experiments of Richers and others on the motion of the pendulum in the equatorial regions (see PENDULUM), also give as convincing proofs of the rotation of the earth, as the aberration of light affords of the revolution of the earth round the sun. Thus the human intellect has triumphed over the evidences of sense, and the opposition of authority.

EARTH-BANKS, in *rural economy*, are a kind of fence, very common in the vicinity of London, and in several other parts of England; where stones cannot easily be procured, they are preferable to other fences, both for soundness and durability.

EARTHQUAKE; a shaking of certain parts of the earth's surface, produced by causes not perceivable by our senses. This motion occurs in very different ways, and with various degrees of violence. Sometimes it is perpendicular, throwing portions of the ground into the air, and making others sink. Sometimes it is a horizontal, undulating motion, and sometimes it appears to be of a whirling nature. Sometimes it is quickly over; sometimes continues long, or recurs at intervals of weeks, days, or months. At one time it is confined within a small circle; at another it extends for many miles. At one time it is hardly perceptible; at another it is so violent, that it not only demolishes the works of human art, but changes the appearance of the ground itself. Sometimes the surface of the ground remains unbroken; sometimes it bursts open into clefts and chasms; and then occasionally appears the phenomenon of the eruption of gases, and also of flames, with the ejection of water, mud, and stones, as in volcanic eruptions.

The eruptions of proper and permanent volcanoes are preceded by, and proportionate to, the agitations of the earth in their neighbourhood. These observations furnish grounds for the conclusion that earthquakes cannot proceed from external causes, but arise from certain powers operating within the circumference or crust of the earth. Moreover, all the phenomena of earthquakes bear so much affinity to those of volcanoes, that there can hardly be a doubt that both proceed from the same causes, acting differently, according to the difference of situation, or different nature of the surface on which they operate.

A volcano differs from an earthquake, principally, by having a permanent crater, and by the re-appearance of the eruptions in the same place, or in its immediate vicinity. All the other phenomena of a volcano, such as the subterranean thunder-like noises, the shaking, raising, and bursting asunder of the earth, and the emission of elastic fluids, the fire and flames, the ejection, too, of mineral substances, all occur, now and then, more or less, in earthquakes as well as in volcanic eruptions, even when at a distance from active volcanoes; and the genuine volcanic eruptions are, as has been remarked, accompanied or announced by shakings of the earth. All our observations go to prove, that volcanic eruptions, earthquakes, the heaving of the ground from within, and the disruption of it in the same way, are produced by one and the same cause, by one and the same chemical process, which must have its seat at a great depth beneath the present surface of the earth.

The most remarkable earthquakes of modern times are those which destroyed Lima, in 1746, and Lisbon, in 1755; in the latter, 20,000 persons were killed. It extended from Greenland to Africa and America. A similar fate befell Calabria, in 1783, the province of Caracas, in South America in 1812, and Aleppo, in Syria, in 1822. Several earthquakes have taken place quite lately, in South America, one particularly dreadful at Lima. The city of Guatemala, also, was nearly destroyed in the spring of 1830, by earthquakes, which continued five days successively.

EARTHS. The term *earth* is applied, in common life, to denote a tasteless, inodorous, dry, uninflammable, sparingly-soluble substance, which is difficultly fusible, and of a moderate specific gravity. Several of the earths are found in a state of purity in nature; but their general mode of occurrence is in intimate union with each other, and with various acids and metallic oxides. Under these circumstances, they constitute by far the greatest part of the strata, gravel, and soil, which go to make up the mountains, valleys, and plains of our globe. Their number is ten, and their names are *silex*, *alumina*, *magnesia*, *lime*, *barytes*, *strontites*, *zircon*, *glucine*, *yttria*, and *thorina*. The four first have long been known to mankind; the remainder have been discovered in our own times.

Silex exists nearly pure, in large masses, forming entire rocks, as quartz rock, and constituting the chief ingredient in all granitic rocks and sandstones, so that it may safely be asserted to form more than one half of the crust of the earth. Alumina is found pure in two or three exceedingly rare minerals, but, in a mixed state, is well known as forming clays and a large family of rocks, usually called *argillaceous*. Lime, an earth well known from its important uses in society, occurs, combined with carbonic acid, in which state it forms limestone, marble, chalk, and the shells of fish. It exists, also, upon a large scale, in combination with sulphuric acid, when it bears the name of *gypsum*. Magnesia is rarely in a state of purity, but enters largely into the composition of some of the primary rocks, especially of the limestones.

The remaining eight (if we except barytes, which, in combination with sulphuric acid, is often met with in metallic veins) are only known to the chemist as occurring in the composition of certain minerals which, for the most part, are exceedingly rare.

The earths are very similar to the alkalies, form-

ing, with the acids, peculiar salts, and resembling the alkalies, likewise, in their composition. They consist of peculiar metals in combination with oxygen, and compose the greatest part of the solid contents of the globe. They differ from the alkalies, principally, in the following peculiarities: they are incombustible, and cannot, in their simple state, be volatilized by heat; with different acids, especially the carbonic, they form salts, insoluble, or soluble only with much difficulty, and with fat oils, soaps insoluble in water. They are divided into two classes, the alkaline and simple earths. The former have a greater similarity to the alkalies. In their active state they are soluble in water, and these solutions may be crystallized. They change the vegetable colours almost in the same way as alkalies, and their affinity for acids is sometimes weaker and sometimes stronger than that of the alkalies. They combine with sulphur, and form compounds perfectly similar to the sulphureted alkalies. With carbonic acid, they form insoluble salts, which, however, become soluble in water by an excess of carbonic acid.

The alkaline earths are as follow: 1. barytes, or heavy earth, so called from its great weight; 2. strontites; both these earths are counted among the alkalies, by many chemists, on account of their easy solubility in water; 3. calcareous earth, or lime, forms one of the most abundant ingredients of our globe; 4. magnesia is a constituent of several minerals. The proper earths are wholly insoluble in water, infusible at the greatest heat of our furnaces, and, by being exposed to heat, in a greater or less degree, they lose their property of easy solubility in acids. Some of them are incapable of combining with carbonic acid, and the remainder form with it insoluble compounds. They are the following: 1. alumine; 2. glucine, which is found only in the beryl and emerald, and a few other minerals; 3. yttria is found in the gadolinite, in the yttrious oxide of columbium, &c.; 4. zirconia is found less frequently than the preceding, in the zircon and hyacinth; 5. silex.

The earths were regarded as simple bodies until the brilliant researches of Sir H. Davy proved them to be compounds of oxygen with peculiar bases, somewhat similar to those of the alkalies, potassium, and sodium. Some of the heavier of the earths had often been imagined to be analogous to the metallic oxides; but every attempt to effect their decomposition or reduction had proved unsuccessful. After ascertaining the compound nature of the alkalies, Davy submitted the earths to the same mode of analysis by which he had effected that fine discovery. The results obtained in his first experiments were less complete than those afforded with the alkalies, owing to the superior affinity between the principles of the earths, as well as to their being less perfect electrical conductors. By submitting them to galvanic action, in mixture with potash, or with metallic oxides, more successful results were obtained; and a method employed by Berzelius and Pontin, of placing them in the galvanic circuit with quicksilver, terminated very perfectly in affording the bases of barytes and lime, in combination with this metal. By the same method, Sir H. Davy decomposed strontites and magnesia; and, by submitting silex, alumine, zircon, and glucine, to the action of the galvanic battery, in fusion with potash or soda, or in contact with iron, or by fusing them with potassium and iron, appearances were obtained sufficiently indicative of their decomposition, and of the production of bases of a metallic nature.

Thorina, the last discovered earth, was decomposed by heating the chloride of thorium with potassium. The metallic bases of the earths approach more nearly than those of the alkalies to the common metals, and the earths themselves have a stricter resemblance than the alkalies to metallic oxides. Viewing them as forming part of a natural arrangement, they furnish the link which unites the alkalies to the metals. Accordingly, many of the more recent systems of chemistry treat of all these bodies as forming a single group under the name of the metallic class. Still (as Doctor Ure justly remarks), whatever may be the revolutions of chemical nomenclature, mankind will never cease to consider as earths those solid bodies composing the mineral strata, which are incombustible, colourless, not convertible into metals by all the ordinary methods of reduction, or, when reduced by scientific refinements, possessing but an evanescent metallic existence. (For a more particular account of the properties of the earths, and of their bases, consult the articles relating to them, respectively, in this work.)

Easel, in the *fine arts*. The frame on which the picture is placed during the progress of painting.

East; one of the four cardinal points of the world, being the point of the horizon where the sun is seen to rise when in the equator. In Italy, and throughout the Mediterranean, the east wind is called the *levante*.

East India Commercial Companies. From the earliest times, the commercial enterprise of the Europeans has been directed towards an immediate intercourse with the East Indies; but the Arabian empire, and its mercantile grandeur, at first, and the dominions of the Persians and Turks at a later period, presented insurmountable barriers. The commercial shrewdness of the Italian republics did not succeed in entirely overcoming these obstacles; and even the Venetian commerce with India, extensive as it was, could not be called direct.

After the Turks had established themselves in Europe, by the conquest of Constantinople, and in Africa, by that of Egypt, the access to India was more completely shut up, and the enterprising spirit of the merchants of Christendom was turned to the discovery of a direct channel to that land of commerce. The west of Europe was delivered from the Saracens, and the warlike spirit which had long been occupied by the contests with the infidels, required some new scene of activity. The great Portuguese prince Henry, surnamed the *Navigator*, first directed this energy towards the eastern ocean; and not half a century had elapsed from the taking of Constantinople, when Vasco de Gama (1498) landed in Hindostan, on the coast of Malabar, and the Portuguese successfully established themselves on those distant shores. The whole commerce of the East Indies was in their hands for nearly a century—the golden age of Portugal. The efforts of Alphonso Albuquerque, Nuno da Cunha and Francis Xavier—the latter with spiritual weapons, and the former by force of arms—will ever be remembered with admiration, even had they not been sung in the verses of Camoens. During eighty years, while the transportation of Indian productions through Genoa, Venice, and the Hanse Towns, was constantly diminishing, Lisbon was the India of the north of Europe.

The English and Dutch obtained their supplies of Indian spices either from Lisbon or from Portuguese merchants in Antwerp. Venice also found herself supplanted by the military power of the Portuguese, and the subjection of her commercial friends, the Saracens. When, however, Philip II., in 1580, united Portugal with the Spanish Monarchy, and soon after commenced his war with England, against whose vessels he closed the ports of his empire, the British merchants were compelled to draw their supplies of Indian produce from the Netherlands. The Dutch took advantage of this circumstance, and raised the price of pepper to three times its former amount. But the revolt of the Netherlands from Spain induced Philip II. to take decided measures against the Dutch commerce also, and the capture of their vessels in the port of Lisbon compelled the Dutch to engage in a direct trade to India: the English soon followed their example. Thus, during the last ten years of the sixteenth century, the foundation was laid in England and Holland, nearly at the same time, of those great commercial corporations, called *East India Companies.* They are distinguished from the Hanseatic league, and other earlier unions of that kind, in being merely associations of individuals uniting for a common commercial purpose, with transferable shares, and not of political bodies; and also by having bought their privileges and rights at once from their own governments, while those of the earlier commercial confederacies were obtained, together with their political privileges, by successive treaties.

As such an extensive commerce in distant parts of the world requires a political power to preserve and protect it, we find our own countrymen, the Dutch, and other smaller East India companies, engaged, soon after their establishment, in labouring to form a political power on the basis of wealth; which, even if it succeeded, would not accord with the politics of the mother country, and would not be able, for any great length of time, to resist the reaction that would arise in the conquered countries. I. The earliest India company was the Portuguese, although essentially different, in its organization, from the others. By the union of Portugal with Spain, the connection between the distant Portuguese governments in India and the mother country became less close. Abuses of every kind, illicit traffic on the part of the viceroys and officers, smuggling, and piracy, became prevalent. The Spanish government perceived that the East India commerce, if continued on account of the crown, would not only be unprofitable, but would occasion an annually increasing loss, and therefore granted the exclusive privilege of the East India trade, in 1587, to a company of Portuguese merchants, in consideration of the annual payment of a considerable sum.

This company, in attempting to enforce its privileges, became involved in disputes, equally disadvantageous to both parties, with the Portuguese government in India, which was engaged in the smuggling trade; and the way for the enterprises of the Dutch and English could not have been better prepared than by this weakening of the Portuguese power. To this may be added the impatience of the Indian nations under the Portuguese yoke, and the jealousy and hatred entertained against both by the Arabians.

The English and Dutch companies found every thing in that state of division which is favourable to the establishment of a third party, by means which, in any other case, would be entirely inadequate. This explains their immediate and brilliant success, notwithstanding the great inferiority of their strength. The Portuguese company, on the contrary, on the breaking out of open war between England and Holland and Spain, soon became unable to pay the annual tribute to the crown, and gradually declined, till, in 1640, on the re-establishment of Portuguese independence by King John IV., of the house of Braganza, it was entirely abolished.—From that time the insignificant remains of the Portuguese commerce with the East Indies have been in the hands of the government, if we except the unsuccessful attempt to form a new company in 1731.

II. Eight years after the establishment of the first Portuguese company, the offer of a Dutchman, Cornelius Houtman, who had been taken prisoner by the Spanish, and had become acquainted with the Portuguese East India trade, induced the merchants of Amsterdam, who had already made three unsuccessful attempts to discover a passage to India through the Northern Ocean, to form a company, under the name of the *Company of Remote Parts,* and send their first commercial fleet round the Cape of Good Hope to India, under the command of Houtman. Four small vessels were equipped with a capital of 70,000 guilders, and sailed the 2nd of April, 1595, from the Texel. The example of Amsterdam was followed in the other United Provinces; but these companies soon became aware that they interfered mutually with each other; and March 20th, 1602, they were united by a charter from the States General, conferring on them the exclusive privilege of trading to the East Indies for twenty-one years, together with all necessary civil and military powers. The former companies remained, in some measure, distinct from each other, and the six cities of Amsterdam, Middleburg, Delft, Rotterdam, Horn, and Enkhuysen, which had made the first attempts, were allowed to continue the commerce from their ports. This company began its operations with a capital of 6½ millions of guilders; 65 directors—divided amongst the different members, in proportion to the amount of shares, so that Amsterdam had twenty-five, Middleburg twelve, and each of the other cities seven—superintended the equipment of the vessels in their respective ports; a committee of fifteen directors, apportioned in the same manner, had the general direction of affairs.

In 1622, the subject of the renewal of the charter being before the States General, it appeared that, during the twenty years of its existence, thirty millions of guilders (that is, more than four times the amount of the original capital) had been divided amongst the stockholders; besides which, a great amount of capital had been vested in colonies, fortifications, vessels, and other property, on which no dividend could be made. These results will not be surprising if we consider how much more favourable was the condition of the East Indies, in every respect, for re-republicans and Protestants than for Catholics and subjects of a monarchy.

The Portuguese acted on the principle, that without a strong military force, and a religion common to the conquered and ruling nation, no permanent commercial connection could be formed; and this system was pursued for a century, sometimes with prudence, but more frequently with great inhumanity. The Dutch, on the contrary, with their indifference to the moral relations of nations, and their

well-conducted commerce, were well calculated to succeed. Their superiority to the English, in their first enterprises, was owing not only to their superior skill by sea, their youthful republican spirit, and the greater amount of their capital, but chiefly to their having carried on all their operations, from the first, with a common capital, while our East India Company, till 1610, was a mere association, each member of which transacted business on his own account, merely conforming to certain general rules, such as the employing the Company's ships.

It has been proved by subsequent results, that a mere money power cannot be upheld without an entire disregard of the claims of humanity; and the example of the first Portuguese conquerors has convinced enlightened men, that the dominion of Europeans in India remains insecure, if not founded on a certain moral, legal, and religious community with the inhabitants of the country. The charter of the Dutch East India Company was continued till 1644; Batavia was founded in a very favourable situation for the traffic with the Spice Islands, the chief branch of the Indian trade; 34—41 freighted vessels annually left the ports of Holland for India; 25—34 merchant vessels, on the average, returned.

The commerce with Japan increased rapidly, and the extension of Portuguese power in the Brazils, after the accession of the house of Braganza to the throne, although a great disadvantage to the Dutch West India Company, promoted the interest of the East India Company, by directing the attention of the Portuguese wholly to America, and leaving free scope to the Dutch in Asia. In 1641, Malacca, the capital of the Portuguese East Indies, fell into the hands of the Dutch, by the treason of the governor.—But the increasing activity of the English and French, and the political and military establishments of the Company, diminished their profits, and it was difficult to raise the 1,600,000 of guilders, which were to be paid to the States General, in 1644, for the extention of the charter till 1665. Soon after, however, the independence of the republic of the United Provinces was secured by the peace of Westphalia—an event which was of great advantage to the Company, and enabled them to found colonies on the Cape of Good Hope.—This was done in the course of 20 years (from 1650), at an expense of 20 millions of guilders. These colonies were a great assistance to the intercourse between Europe and India, and richly repaid the expenses incurred.

In 1658 the conquest of Ceylon was completed, after a vigorous defence by the Portuguese; and the Tartar revolution in China occasioned the settlement of 30,000 Chinese, who would not submit to the new government, in the Dutch island of Formosa. These proved a valuable accession to the population. Although the direct commerce with China had to struggle with insurmountable difficulties, the indirect communication through these emigrants, who were well acquainted with the country, and the influx of Chinese productions from all sides into Batavia, amply recompensed the Company. They were, however, deprived of this valuable island in 1661, by a Chinese adventurer, named Kaxinga, whose family afterwards ceded it to the Emperor of China.

The energy of the Company seemed to be excited by this loss. In 1663, the most valuable settlements of the Portuguese on the coast of Malabar were taken; and, in 1666, by the conquest of Macassar, the object of the exertions of 70 years, they obtained the monopoly of the spice trade. At this time the civil and military expenses of the Company, exclusive of the expenses of the war, amounted to 3½ millions of guilders.

In 1665, after much opposition, the charter was renewed till 1700, on condition of the payment of a large sum into the treasury; and the report of the Company showed an almost inconceivable extention of commerce.—Their factories extended from the Cape of Good Hope to the coasts of Arabia and Persia. They were masters of all the important settlements of the Portuguese, from Surat, on the Malabar coast Ceylon, with its cinnamon and ivory; the pearl fishery and cotton trade on the coast of Coromandel; Bengal and Orissa, with their silks and cottons, rice, sugar, saltpetre, &c., were in the hands of the Company, as was also the commerce with Pegu, Siam, and Tonquin, only interrupted by some temporary accidents. They obtained valuable supplies of silver and copper from Japan, carried on an extensive trade in spices with Amboyna, the Banda Islands, and the Moluccas, &c. Malacca, the principal seat of the Portuguese trade, appeared, by this report, to be on the decline, the expense of protection being disproportioned to the size of the place; and the Straits of Sunda, on which Batavia is situated, had superseded the Straits of Malacca, as the general passage to the more distant parts of the East.

The charter of the Company has since been several times renewed, and always on condition of the payment of large sums; from 1701—40; then till 1775; and in 1776 for 30 years more, for the sum of two millions of guilders, and the annual payment of 360,000 guilders.

Avarice and cruelty, which increased with the gradual decay of the republican spirit, and the decline of simple and moderate habits; a shameless system of intrigue towards their allies, and particularly their incapacity to appreciate the moral and religious character of the nations of India; and, finally, the renewed vigour of the British Company at the commencement of the 18th century, and the change in the European demand; the preference given to other spices;—these are the principal causes of the decline of the Dutch East India Company. In the 18th century, their annals abound with relations of conspiracies, insurrections, and generally unsuccessful wars; and, in 1781, we find them so completely broken up by the war with England, and by enormous political expenses, that the States General, notwithstanding their own difficulties, were obliged to assist them with a loan.

In the first revolutionary war, the Company lost most of their possessions, and were obliged to suspend the payment of their dividends in 1796. They had scarcely taken possession of what was restored to them by the peace of Amiens, 1802 (this country retaining only Ceylon), when every thing was lost by the new war; and at the general peace they retained none of their early East India possessions but the governments of Batavia and Amboyna, Banda, Ternate, Malacca, Macassar, and some scattered factories on the coasts of Malabar and Coromandel. The Cape of Good Hope and Ceylon were lost to them for ever. At their commencement, the Dutch East India Company had enjoyed the advantage of all the Portuguese establishments; their forts, magazines,

artillery, and provisions for defence, their commercial and political relations, and an immense booty which the capture of the Portuguese ships on every sea afforded them; while, on the contrary, the English had to struggle for a century with the difficulty of gradually gaining the ground on which to plant their commercial lever. But the very circumstance of their slow progress gave a firmer footing to their power.

III. The history of our own East India Company may be divided into four periods. During the first fourteen years, its members were, in a great measure, independent. In the following ninety-five years, although it had a common capital, its operations were confined by the superiority of the Dutch in the Indian seas, by the civil wars at home, and particularly by the calling in question of its exclusive privileges, which were merely a royal, and not a parliamentary grant. For the succeeding forty years, it enjoyed all its rights undisputed, and founded on parliamentary authority, but confined to mere commercial transactions. And, finally, during the subsequent seventy years, its political power was developed.

1. Period from 1600 to 1613. Our countrymen, in their first attempts to reach India, directed their course to the north-west, as the Dutch did to the north-east. John Cabot, in the employ of Henry VII., had discovered Newfoundland, and the coasts of North America, in 1497. In 1553, his son, Sebastian Cabot, under Edward VI., engaged in a second enterprise of this kind. The king chartered a company, which, with a capital of 6000*l.* equipped three vessels, for the discovery of a northern passage to India. Part of this expedition was lost in the Northern Ocean; another part landed on the northern coast of Russia, and formed commercial connections which gave rise to the English Russian Company, in the same manner as the Hudson's Bay Company owes its establishment to the attempts to discover a north-west passage, which have been continued to the present day. The British, at the same time, endeavoured to penetrate to India, directly, by land, and, at least, to rival the Venetians, if they could not contend with the Portuguese. This was the main object of the Turkish Company, established in 1581, which, however, soon became convinced of the impracticability of the attempt, and was induced, by Sir Francis Drake's account of his circumnavigation (1591), to send out three ships to India, under the command of Captain Raymond, on the route of the Portuguese. This attempt, and that made by Robert Dudley, in 1596, failed entirely.

The Spanish war, the shutting up of Lisbon, and the avarice of the Dutch, gave, however, a new vigour to the enterprise of the London merchants, and, Sept. 22, 1599, a society was formed in London, which, in the course of rather more than two centuries, has acquired the greatest power of any commercial association on record. The original capital amounted to 30,133*l.* sterling; and Queen Elizabeth, Dec. 31, 1600, granted to the Governor and Company of Merchants of London trading to the East Indies, for fifteen years, the exclusive right of trading to all countries from the Cape of Good Hope eastward, to the Straits of Magellan, excepting those which were in the possession of friendly European powers.

Until 1613, the Company consisted merely of a society subject to particular regulations; each member managed his affairs on his own account, and was only bound to conform to certain general rules. Notwithstanding the disadvantages of this arrangement, the profits of eight voyages amounted to 171 per cent.

2. Period from 1613 to 1708. At this time (1613), the capital was united, and the constitution, in consequence, became more aristocratic; the largest stockholders having the principal management, and the great mass of the stockholders having only a nominal control in the general meetings. These latter, in reality, had only in view speculation in the shares. The concerns of the Company were so prosperous, that, in the course of four years, the shares rose to the value of 203 per cent., and the Dutch became desirous, though they did not succeed, to unite with it against the Portuguese. Its factories were extended to Java, Sumatra, Borneo, the Banda Islands, Celebes, Malacca, Siam, the coasts of Malabar and Coromandel, but chiefly to the states of the Mogul, whose favour the Company had very prudently secured. Their success was such, that, a new subscription being opened in 1616, the amount raised was 1,629,040*l.* But, in 1627, complaints were made of bad management, and abuses of all kinds, particularly in regard to the private commerce of the officers, which has always been of the greatest disadvantage to all such companies.

The opposition to the royal authority under the Stuarts, brought into question the monopoly of the Company which rested on a royal grant. The kings themselves contributed to raise these doubts, by granting to individuals the privilege of trading to India, much to the disadvantage of the Company. During the time of the Commonwealth, the public opinion became very strong against monopolies, and Cromwell, by destroying the charter, in 1655, attempted to make the East India trade free. But this was impracticable. To give up the Company, was to destroy the whole basis of power and influence obtained in India. After the restoration of the royal family, the charter which even Cromwell had been obliged to renew, was again in full force.

During the short period which elapsed from this time to the revolution of 1688, the Company obtained, by the acquisition of Madras and Bombay, the predominance on the coasts of Malabar and Coromandel, and laid the foundation for the extension of its possessions into the interior of Hindostan, and for that power which rose on the ruins of the empire of the great Mogul. The affairs of the Company were not, however, in a prosperous state; and, soon after the revolution, the question was started, whether the King could impose restrictions on commerce by a charter, and whether a sovereign, who possessed the rights of sovereignty conditionally, could confer them on a privileged company. The consequence was, that, the Company not being able to perform their obligations, on account of the losses occasioned by wars, infidelity of officers, extravagance, &c., Parliament granted a charter to a new East India Company, in 1698, on condition of a loan of 2,000,000*l.* sterling, at 3 per cent., for the service of the state. But the great contentions between the two companies soon made it necessary to unite them, and a union was effected in 1708.

3. Period from 1708 to 1748. In 1708, an act of parliament was passed, establishing the English East

India Company on its present footing, under the title of The United Company of Merchants of England trading to the East Indies. Its exclusive privileges were granted till 1726, after which it was determinable upon three years' notice. The capital was raised by the sale of the shares: one share (of the value of 500*l.*) gave the holder a vote in the "General Court;" four shares, or stock to the amount of 2000*l.*, rendered the holder eligible as one of the twenty-four "directors," who managed the government of the Company. The shares being transferrible, the great mass of stockholders are constantly changing, and take no personal interest in the affairs of the Company, but merely speculate in the shares. The wnole management is left exclusively in the hands ot the directors, and all the numberless abuses of an oligarchical constitution are readily introduced.

The local affairs of the Company were intrusted to the three councils of Madras, Bombay, and Calcutta, while the general direction was retained in England. But, as every thing depended ultimately on the local officers in India, the pernicious abuse prevailed of attempting to secure the fidelity of the superior officers, by allowing them to appropriate to themselves the inferior lucrative posts. The renewal of the charter in 1732 was not obtained without great difficulty, and against a powerful opposition. The Company therefore thought it adviseable, in 1744, to advance 1,000,000*l.* sterling, at 3 per cent., for the service of government, in consideration of an extension of their grant till 1780.

4th Period. The political power of the English in India commenced in 1748. The French had already set the example. In 1746, a French battalion had destroyed the army of the Nabob of the Carnatic, and, soon after, the French officers succeeded in disciplining Indian troops according to the European method. The inferiority of the native Indian troops opposed to European soldiers, and the facility of instructing Indian soldiers, known by the name of *Sepoys*, in the European discipline, was thus proved. Ambition and avarice, political and mercantile cunning, could now act on a larger scale; and the independence of the Indian princes was gone whenever this trading company, which was already encroaching upon all the rights, both of the rulers and the people of those countries, should establish a permanent military force. Thus far, the military organization of the Company had been merely on the defensive: it now became able to act offensively; and the entire difference of the European and Indian notions of law could never fail to furnish opportunities to put this new means of power into action.

The rights of succession, and all the rights of princes, subjects, and families, were so much disputed on the different principles of the Indian, Mohammedan, and British laws, that the Company (which often interposed as arbitrator) easily succeeded in extending their legal jurisdiction. If called to account in Europe for any of its undertakings, it was easy to uphold the correctness of its conduct, politically, on the ground of self-defence, which, at the distance of several thousand miles, could not be called in question; and, in legal matters, by taking advantage of the impenetrable labyrinth of law. Edmund Burke, who experienced, in the case of Hastings, this impregnability of the Company, accused them justly "*of having sold every monarch, prince, and state in India, broken every contract, and ruined every prince and every state who had trusted them.*"

The high officers in India, whatever great names may appear among them, become despotic from situation: 1. because each receives an inheritance of injustice, which must be maintained; 2. because public opinion has no influence; 3. because no moral and religious connection, nor even that of language, exist between the ruled and the rulers; 4. because no fear of dangerous insurrections can exist, on account of the great division of the Hindoo and Mohammedan classes and interests; 5. because the officers of the Company have no object but to make money, with a view of spending it in England, as soon as they have accumulated sufficient to satisfy their wishes, and, therefore, are not disposed to make opposition against abuses.

In 1749, the robberies of the Company began with its protection of the pretender of Tanjore. Under pretence of illegitimacy, the nabob of this district was driven out, for the purpose of obtaining some cessions of territory, and then restored, on making farther concessions. The rapid progress of the Company in the art of extending their possessions, appears from their treaties with Surrajah-Dowlah, the Nabob of Bengal, in 1757, when large and rich provinces were the reward of their faithless policy. This enlargement of territory caused such enormous expenditures, the difficulties of governing increased so greatly with the increase of power, the numerous officers became so much more independent, rapacious, and disobedient, that the finances of the Company suffered.

The direction in London was now nothing more than a mere control of the real government, which had its seat in India. Its orders were antiquated before they reached Calcutta. The governors having the advantage of being on the spot, it was to be expected that they would obey only when personal interest required it. Thus the repeated prohibition to carry on a traffic in the interior, with salt, tobacco, and betel nuts, was entirely disregarded, with the express consent of the East Indian councils; and, long after the directors had forbidden the officers of the Company to accept presents from the Indian princes, it was proved that they had openly received them, to the amount of 6,000,000*l.* from the family of the Nabob of Bengal alone. On this account, the internal situation of the Company became constantly worse, and, in 1772, it was compelled to raise a loan, at first of 600,000*l.*, from the Bank, and afterwards of 1,400,000 from the Government, for its current expenses. The public dissatisfaction was the greater, as it had been expected that the extension of British power in India would have brought much wealth into the mother country. At the same time, great complaints were made against the unprincipled conduct of the Company's officers towards the princes and people of India; and, as the expected advantages appeared not to have been obtained, it now began to be proclaimed, that the rights of humanity had been trampled upon.

The popular hatred was unjustly directed against the directors; their power was to be limited; they, who had to manage a disobedient world, were to be still more cramped. Control was demanded; as if a control which sympathises with the oppressors, and has no connection with the oppressed, could avail any thing; as if oppression were a single act, which

might be prevented by superintendence, or punished like a crime: and what would be the effect of a controlling power whose commands would require more than half a year to be conveyed to the spot, and as much more time before the result could be known in Europe? And, if the Company had obtained a power by force, which could only be preserved by the same means, on what principle should the control act?—Burke's famous, but unsuccessful struggle of seven years, against Hastings, and in the cause of humanity in India, proved that the only possible control of the officers in India, is the public opinion of the British nation. One party asserted that all would be well as soon as the Company divided its power with the ministry. Another party maintained that all that was wanting to the Hindoo was the benefit of British law.

Some thought it would be sufficient merely to increase the difficulty of becoming a director. Thus the incomplete reform of 1773 took place. Instead of 500*l.*, 1000*l.* was made necessary to give the right of a vote, 3000*l.* for two votes, 6000*l.* for three votes, and 10,000*l.* for four votes. Only six directors were to be annually elected. A governor-general, with four counsellors (at first named by Parliament, that is, by the ministry, but afterwards by the directors, for five years), was to be placed over the provinces of Bengal, Bahar, and Orissa; the other provinces were to be dependent upon him.

As a counterpoise to this concentration of power, a supreme court was established at Calcutta, with a chief justice and three associate judges, who were independent of the Company, and were appointed by the crown. All the civil and military correspondence of the Company was to be communicated to the ministry. Under the old system, in many disputed cases, conscience, or, at least, common sense, had decided; but now, the introduction of a new and strange legal constitution occasioned the ruin of all legal relations. The court decided in the case of every complaint made against any individual who was directly or indirectly in the service of the Company, as well as all complaints relating to contracts in which the parties had submitted to its jurisdiction.

If we consider that nothing was more uncertain than the personal condition of the Indian and Mohammedan inhabitants of Hindostan; that the Company governed some provinces immediately, others indirectly, by means of nabobs; that the zemindars were sometimes considered as the independent nobility of India, sometimes as officers of the Company, &c.—it follows, that the court could take all cases into its own hands, or decline them at pleasure. Immediately after its establishment, it gave a specimen of the spirit by which it was actuated. Nunkomar, who had accused the governor-general, Hastings, was convicted, on insufficient grounds, of forgery, and hanged. On the whole, the history of the British East India trade justifies the assertion that, except Burke, and the family of Wellesley, scarcely a single Englishman has ever entered completely into the spirit of the people of India. When the inefficacy of the measures of 1773 was sufficiently proved, and the finances of the Company again suffered by the American war, the establishment of a board of control was again discussed in Parliament, and on broader grounds; from 1782 to 1784, the greatest men of England were engaged on this important subject. The famous East India bill of Fox, which proposed seven commissioners, to be appointed by Parliament, and invested with supreme power, and, as it were, the right of protection over India, could not be agreeable to the court, as the principal object of the bill was to deprive the crown of all influence on Indian affairs, and to place an intermediate power between the king and India. Pitt's project, therefore, took effect.

A *board of control* was erected, dependent on the crown, authorized to superintend the civil and military government and the revenues of the Company, and to transmit the dispatches of the directors to the different presidencies. The salaries of the governor-general, the president, and the council were fixed by the king.

We have thus given a historical outline of the constitution of the Company. The power of control in England, so far as any exists, is in the hands of the ministry; the particular direction of the government is subjected to the Company. It is certain that, since the establishment of the board, much less is known of Indian affairs than formerly. The ministers have not the same grounds for occasional investigation; the stockholders, in the general meetings of the Company, can effect nothing, even if desirous to interfere, while the board and the directors agree; and this agreement is the more firmly established, as a committee of secrecy exists, consisting of three directors, which can consult and decide, with the concurrence of the board, without any communication with the other directors. The improvement of the moral condition of British India is impossible, while the fear of a result like that which occurred in the case of the North American colonies, prevents the regular colonization and establishment of British subjects in India. A race of Englishmen born in India could alone succeed, in the course of time, in bringing order and harmony into the jarring interests and relations of the country. The political importance of the East Indies, in their present state, to England, is too great to allow us to expect any immediate improvement in the condition of India.

A taxable population of 83,000,000 of inhabitants, with 40,000,000 under dependent native princes; an army of 200,000 men, in the service of the Company; about 16,000 civil officers; an annual export of about 14,000,000*l.*, and an import to the same amount, from all parts of the world, are objects which outweigh all moral considerations. This gigantic political-mercantile association might exist as long as a small military power is sufficient to prevent a great nation from attempting to throw off the yoke; as long as the system *de faire le commerce en sultan et de faire la guerre en marchand* can survive; as long as the pretensions of the *metis*, the offspring of European fathers and Indian mothers, do not increase; and the Indians and Mohammedans remain ignorant of the real weakness of their oppressors; that is, as long as the course of nature is reversed. Since 1813, all British subjects have been permitted to trade to the East Indies, under certain conditions advantageous to the Company, which has, however, claimed the exclusive commerce in tea. It appears that the revenue of the British possessions in India is greater than that of any European state, excepting France and England. In 1827-28, it amounted to 23,035,164*l.* in 1828-29, it is estimated at 23,350,317*l.* The interest on the debt is about 2,000,000*l.* yearly; the

total interest on the debt and charges, including those paid in England, and the expenses of the island of St. Helena, was 26,314,344*l.* in 1827-28, and 23,994,503*l.* in 1828-29; the surplus of charge above revenue was, in 1825-26, over three millions; the estimated surplus revenue in 1829, 1,318,593*l.* Before the Burmese war, there was a surplus of revenue over expenditure of one million and a half; but in the twenty years preceding 1828-29, there are only six which show a surplus revenue. The total assets of the Company, including property of every description, amounted to 18,406,039*l.* The rate of dividend, since 1793, has been 10½ per cent. It is believed that the value of American imports from England into China amounts to 800,000 dollars, whilst that of the Company amounts to 800,000*l.* The Company's tonnage to China had increased, for the last nine or ten years 5000 on an average.

The present value of the trade possessed by the British East India Company, with reference to the private trade, will be best understood by reference to a document printed by order of the House of Commons.

Between India and China, we find a total of 4,229,354*l.* sterling, for one year. This includes both imports and exports, out of which the Company have but 433,388*l.*, and the remainder belongs to private individuals. The exports and imports, between England and China, on account of the Company is rather less than two millions and a half pounds sterling.

The amount of the population of the British East Indies cannot, of course, be known with any thing like accuracy; but the following is probably as near an approximation as can be made:—In the Bengal presidency, 58,000,000; Madras presidency, 16,000,000; Bombay presidency, 11,000,000; total British, 85,000,000; subsidiary and dependent (say), 40,000,000; outports in the bay, &c. (say), 1,000,000; total under British control, 126,000,000; independent states, but controlled by the British arms (say), 10,000,000; approximate total, not European, 136,000,000; total Europeans, about 40,000; about one European to three thousand four hundred natives, or, where they have the whole command of the government and revenue, one European to two thousand one hundred and twenty-five natives.

As the charter of the East India Company is about to expire, no doubt every effort will be made by their friends to ensure its renewal, and it is most probable that they will effect their object; but common sense should teach those who legislate for the commercial interests of this country, not to continue the whole of those oppressive regulations which now shackle our trade with so large a portion of the globe. The morality of the question, as to whether we should keep a mighty empire in darkness merely because they would break the bonds which now fetter them the moment they became intellectually enlightened, requires but little discussion. The political power of the Company appears rather beneficial than otherwise to the natives, but they must be taught to wield it with a different spirit. A free press, the only basis of free institutions, must be established, and the natives of this country must be allowed to settle in the Company's territories, as they do in any other colonies belonging to Great Britain, without the Indian government having the power, as in the case of Mr. Buckingham, to issue a species of *lettre de cachet*, for their seizure and removal.

Since writing the above, we find that the charter is likely to be renewed, but in a modified form. Colonization is to be permitted, though without allowing a free trade with the interior, and the China trade is to be thrown entirely open.

IV. The French, Danish, and Swedish East India companies have been of little importance, even in their most flourishing state, to the commerce of the world. The French, established in 1664, could not succeed; in 1796, the trade was again thrown open. A new company established in 1785, expired in 1791. The East India company in Denmark established in 1618, and several times renewed, finally surrendered its possessions to the king in 1777. The company has now only the Chinese trade. The Swedish East India Company established in 1731, and renewed in 1766 and 1786, still exists at Gottenburg. For every voyage it pays 75,000 dollars in silver to the crown, to which, on its establishment, it was obliged to advance 3,000,000 dollars in silver, of which one million, not on interest, is merely a security, and the other two millions are considered as a loan.

East India Fly (*lytta gygas*). This species of cantharides has been tried in America; and they were found to be exceedingly active as vesicatories, and never failed in their effect. They produce a vesication, in general, much earlier than the Spanish fly, and, from being found so much more active, only one half the quantity is added in making the *emplastrum cantharidis*.

Eau de Cologne, or water of Cologne, a fragrant water, made originally, and in most perfection, in Cologne. Formerly many wonderful powers were ascribed to this water, but it was probably never so much in demand as at present, in Europe and America, and numberless recipes have been given for its manufacture. It was invented by a person named *Farina*, in whose family the secret, as they say, continues to be preserved, since chemistry has not been able as yet to give the analysis of it. It is imitated, however, everywhere. The consumption of this perfume has increased, and there exist at present, fifteen manufactories of it in Cologne, which produce several millions of bottles yearly; much, also, is manufactured at Paris, in Saxony, and other places. One of the many recipes to make *eau de Cologne* is the following:

Alcohol, or spirit of wine, at 30° . . 2 pints.
Oleum neroli*
——— de cedro
——— de cedrat
——— cort aurant } . . . . 24 drops.
— citri
——— bergamot
——— rosmarin
Seed of small cardamum . . . . 2 drachms.

Distil it in a sand-bath, until three-fourths of the alcohol have evaporated.

Eau de Luce (*aqua Lucia*, or *spiritus salis ammoniaci succinatus*); invented by a person named *Luce*, at Lille, in Flanders; a volatile preparation, thus made: ten or twelve grains of white soap are dissolved in four ounces of rectified spirit of wine, after which the solution is strained, and a drachm of rectified oil of amber is added, and the whole is filtrated. Afterwards, some strong volatile spirit of sal ammonia should be mixed with the solution.

* Ethereal oil of orange-flowers.

Eaves; the edges of the roof which overhang a house.

Ebb; the reflux of the tide toward the sea.

Ebony; a kind of wood, extremely hard, and susceptible of a very fine polish, which is much used in mosaic, inlaying, and other ornamental works. Its colour is red, black, or green. The black is most esteemed, and is imported principally from Madagascar and the Isle of France. *Red ebony*, so called, though its colour is brown, striped with black, is less compact, and is also brought from Madagascar. The green is softer than either of the preceding, yields a fine green tincture, which is employed in dyeing, and is brought from the West Indies, particularly from Tobago, as well as from the above-mentioned islands. The best is jet black, and free from knots, or reddish veins. Ebony is imitated by subjecting some hard kinds of wood, especially that of the pear tree, to a hot decoction of galls, and, when this is dry, applying ink with a stiff brush; a little warm wax is then used to give it a polish: another method is, by heating and burning the wood.

Ebullition; the act of boiling up with heat; any intestine violent motion of the parts of a fluid. In water, under ordinary circumstances the phenomena of ebullition do not take place till the fluid arrives at 212°.

Eccentricity *of the planets*; the distance between the sun and the centre of the orbit in which the planet moves.

Ecchymosis, in *surgery*. This term signifies a livid or blue discoloration of the skin, caused by the rupture of vessels, and extravasation of blood. Contusions are always attended with a degree of ecchymosis.

Echelon (*French*; a ladder or stairway); used in military language. A battalion, regiment, &c., marches *en échelon*, or *par échelon*, if the divisions of which it is composed do not march in one line, but on parallel lines. The divisions are not exactly behind each other, but each is to the right or left of the one preceding, so as to give the whole the appearance of a stairway. This order is used if the commander wishes to bring one part of a mass sooner into action, and to reserve the other. If the divisions of the *échelon* are battalions, these are generally from 100 to 200 steps from each other.

Echo. When the waves of sound strike against a distant, hard surface, they are reflected, and heard again after a short space; this repetition is called *echo*. If the sound is repeated several times, which is the case when it strikes against objects at different distances, many echoes are heard. This phenomenon is not caused by a mere repulsion of the sonorous particles of air, for then every hard surface would produce an echo; but it probably requires a degree of concavity in the repelling body, which collects several diverging lines of sound, and concentrates them in the place where the echo is audible, or, at least, reflects them in parallel lines, without weakening the sound, as a concave mirror collects in a focus the diverging rays of light, or sometimes sends them back parallel.—Still, however, the theory of the repulsion of sound is not distinctly settled, probably because the nature of reflecting surfaces is not sufficiently known. The reflecting surface must be at a certain distance, in order that the echo may come to the ear after the sound, and be yet distinctly separated from it. (See Acoustics.)

Echo, in *music*; the repetition of some part of an air in a very low, soft, manner, in imitation of a real echo.

Echometer, in *music*; a kind of scale or rule, with several lines thereon, serving to measure the duration and length of sounds, and to find their intervals and ratios.

Eclipsareon, in *astronomy*; an instrument invented by Mr. Ferguson for exhibiting the duration and character of eclipses.

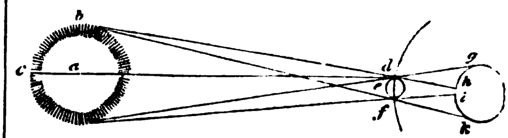
Eclipse. *An Eclipse of the Moon* is a privation of the light of the moon, occasioned by an interposition of the earth between the sun and the moon; consequently, all eclipses of the moon happen at full moon; for it is only when the moon is in opposition, that it can come within the earth's shadow, which must always be on that side of the earth which is from the sun. The earth being in the plane of the ecliptic, the centre of its shadow is always in that plane: if, therefore, the moon be in its nodes, that is, in the plane of the ecliptic, the shadow of the earth will fall upon it. This shadow, being of considerable breadth, is partly above and partly below the plane of the ecliptic; if, therefore, the moon in opposition be so near one of its nodes that its latitude is less than half the breadth of the shadow, it will be eclipsed. But, because the plane of the moon's orbit makes an angle of more than five degrees with the plane of the ecliptic, it will frequently have too much latitude at its opposition to allow it to come within the shadow of the earth.

An Eclipse of the Sun is an occultation of part of the face of the sun, occasioned by an interposition of the moon between the earth and the sun; thus all eclipses of the sun happen at the time of new moon. The dark or central part of the moon's shadow, where the sun's rays are wholly intercepted, is called the *umbra*, and the light part, where only a part of them are intercepted, is called the *penumbra*; and it is evident that, if a spectator be situated on that part of the earth where the umbra falls, there will be a total eclipse of the sun at that place; in the penumbra there will be a partial eclipse, and beyond the penumbra there will be no eclipse. As the earth is not always at the same distance from the moon, if an eclipse should happen when the earth is so far from the moon that the rays of light proceeding from the upper and lower limbs of the sun cross each other before they come to the earth, a spectator situated on the earth, in a direct line between the centres of the sun and moon, would see a ring of light round the dark body of the moon; such an eclipse, as we stated in the article Astronomy, is called *annular*. People situated in the penumbra will then perceive a partial eclipse; and an eclipse can never be annular longer than 12 minutes 24 seconds, nor total longer than 7 minutes 58 seconds; nor can the duration of an eclipse of the sun ever exceed 2 hours.

The sun being larger than the earth, the earth's shadow is a cone, whose base is on the surface of the earth, and the moon is eclipsed by a section of the earth's shadow. If the earth were larger than, or equal to, the sun, its shadow would either perpetually enlarge, or be always of the same dimension; but, in this case, the superior planets would sometimes come within it, and be eclipsed, which never happens. Therefore the sun is larger than the earth, and produces a shadow from the earth of a conical form, which does not extend to the orbit of Mars. An

eclipse of the moon is *partial* when only a part of its disc is within the shadow of the earth; it is *total* when all its disc is within the shadow; and it is *central* when the centre of the earth's shadow falls upon the centre of the moon's disc. Now the nearer any part of the penumbra is to the umbra, the less light it receives from the sun; and, as the moon enters the penumbra before she enters the umbra, she gradually loses her light, and appears less brilliant. The duration of an eclipse of the moon, from her first touching the earth's penumbra to her leaving it, does not exceed five hours and a half. The moon does not continue in the earth's umbra longer than three hours and three quarters in any eclipse, neither is she totally eclipsed for a longer period than one hour and three quarters. As the moon is actually deprived of her light during an eclipse, every inhabitant upon the face of the earth who sees the moon sees the eclipse. An eclipse of the sun, as we have said, happens when the moon, passing between the sun and the earth, intercepts the sun's light; and the sun can only be eclipsed at the new moon, or when the moon, at its conjunction, is in or near one of its nodes. For, unless the moon is in or near one of its nodes, it cannot appear in or near the same plane with the sun, without which it cannot appear to us to pass over the disc of the sun. At every other part of its orbit, it will have so much northern or southern latitude as to appear above or below the sun. If the moon be *in* one of its nodes, having no altitude, it will cover the whole disc of the sun, and produce a total eclipse, except when its apparent diameter is less than that of the sun; if it be *near* one of its nodes, having a small degree of latitude, it will only pass over a part of the sun's disc, or produce a partial eclipse. In a total eclipse of the sun, the shadow or umbra of the moon falls upon that part of the earth where the eclipse is seen, and a spectator, placed in the shadow, will not see any part of the sun, because the moon will intercept all the rays of light coming directly from the sun. In a partial eclipse of the sun, a penumbra, or imperfect shadow, of the moon, falls upon that part of the earth where the partial eclipse is seen. Were the orbit of the earth and that of the moon both in the same plane, there would be an eclipse of the sun every new moon, and an eclipse of the moon every full moon. But the orbit of the moon makes an angle of five degrees and a quarter with the plane of the earth's orbit, and crosses it in two points, called the *nodes*. Astronomers have calculated that if the moon be less than 17° 21′ from either node, at the time of new moon, the sun may be eclipsed; or if less than 11° 34′ from either node, at the full moon, the moon may be eclipsed; at all other times there can be no eclipse, for the shadow of the moon will fall either above or below the earth at the time of new moon; and the shadow of the earth will fall either above or below the moon at the time of full moon. Eclipses are now of certain calculation. It was, however, believed by the ancients that their number depended on chance. An eclipse of the sun begins on the western side of his disc, and ends on the eastern; and an eclipse of the moon begins on the eastern side of her disc, and ends on the western. The average number of eclipses in a year is four, two of the sun and two of the moon; and, as the sun and moon are as long below the horizon of any particular place as they are above it, the average number of visible eclipses in a year is two, one of the sun and one of the moon.

The precise character of this species of eclipse can only be explained by reference to a diagram.



The sun is represented at *a*, and a ray at *b* is seen to pass from the extremity of the sun's disc. Another ray passing from the centre, or from the direction of *c*, ends at *d*; for there the light will be intercepted by the moon, *e*, and the same will also occur by the ray *b f k*. The *umbra* formed on the earth's surface will thus be much smaller than the moon, while the *penumbra*, on the contrary, will considerably exceed it in magnitude. The size of the umbra is shown at *h i*, and the penumbra at *g k*. Now, the portion of a circle, delineated at *d f*, represents the moon's orbit, and it will be obvious that, if the orbit was always in the same relative position with reference to the sun and earth, eclipses would be of very frequent recurrence; such, however, is not the fact, as it is either above or beneath that position on most occasions.

Ecliptic; the sun's path; the great circle of the celestial sphere in which the sun appears to describe his annual course from west to east. The Greeks observed that eclipses of the sun and moon took place near this circle; whence they called it the *ecliptic*, from *eclipses*. By a little attention, we shall see that the sun does not always rise to the same height in the meridian, but seems to revolve round the earth in a spiral. We likewise observe every day, at its rising and setting, new stars in the neighbourhood of the sun. It will also be seen that the sun is in the equator twice a year; about March 22 and September 22.

The points of the equator at which the sun is stationary, on these days, are at the intersection of the equator with the ecliptic. June 21, the sun reaches its greatest height in the heavens; and December 21, it descends the lowest. Because the sun appears to turn back at these points, they are called the *tropics*; and the times at which the turning appears to commence are called *solstices* (*solstitia, solis stationes*). At these points, the sun has attained its greatest distance from the equator. These four points, the equinoctial and solstitial points, are distant from one another a quarter of a circle, or 90 degrees. Each of these quadrants, or quarters of a circle, is divided into 3 equal arcs of 30 degrees; thus the whole ecliptic is divided into 12 equal arcs or signs: these receive their names from certain constellations through which the ecliptic passes, and which extend each 30 degrees, and are some of them of a very picturesque character.

The constellations, or 12 celestial signs, succeed one another in the following order, from the vernal equinox, reckoned towards the east:

♈ Aries, March 20.
♉ Taurus, April 20.
♊ Gemini, May 21.
♋ Cancer, June 21.
♌ Leo, July 22.
♍ Virgo, August 23.
♎ Libra, September 23.
♏ Scorpio, October 23.

♐ Sagittarius, November 22.
♑ Capricornus, December 21.
♒ Aquarius, January 19.
♓ Pisces, February 18.

The days of the month annexed show when the sun, in its annual revolution, enters each of the signs of the zodiac. The 30 degrees in every sign are divided into minutes and seconds, not reckoned separately, but after the signs. An arc of the ecliptic, for example, of 97° 15′ 27″, reckoned from Aries, eastward, is called 3 signs, 7° 15′ 27″ long, or, what is the same thing, it terminates in 7° 15′ 27″ of Cancer. In this way the longitude of the stars is given.

The ecliptic, like all circles, has two poles, which move about the poles of the earth every 24 hours, and in this manner describe the polar circles. What appears to be the path of the sun, however, is, in reality, the path of the earth. The planets and the moon revolve in different planes; but these are inclined at only a very small angle to the plane of the ecliptic; hence these bodies can be but a small distance from the ecliptic. The plane of the ecliptic is very important in theoretical astronomy, because the courses of all the other planets are projected upon it, and reckoned by it.

By the obliquity of the ecliptic, we understand its inclination to the equator, or the angles formed by the planes of these two great circles. This angle is measured by the arc of a third great circle, drawn so as to intersect the two others perpendicularly in the points at which they are farthest apart. These points of intersection are 90 degrees distant from those points at which the equator and ecliptic intersect each other, i. e. the solstitial points. The ancients endeavoured to measure the obliquity of the ecliptic. According to Pliny, it was first determined by Anaximander; according to Gassendi, it had been ascertained by Thales. The most celebrated measurement of this obliquity, in ancient times, was made by Pytheas, at Marseilles. He found it, 350 B. C., to be 23° 49′ 23″. A hundred years later, according to Ptolemy, Eratosthenes found it to be 23° 51′ 20″. Various measurements have subsequently taken place, even down to our own time; and it is remarkable that almost every measurement makes the angle less than those which preceded it. Among the modern estimates are that of Cassini, 23° 28′ 35″; of La Caille, 23° 28′ 19″; of Bradley, 23° 28′ 18″; and of Mayer, 23° 28′ 16″: the observations of Delambre, Maskelyne, Piazzi, Bessel, and others, give this important astronomical element, for the year 1800, at 23° 27′ 56″.

In respect to the decrease of the inclination of the ecliptic, the most celebrated astronomers of our time, as Lalande, adopted the opinion that this decrease continues uninterruptedly. Louville determined the annual decrease to be 1′, La Caille 44″, and Lalande 33″. Several philosophers, of modern times, concluded, from these observations, that the equator and the ecliptic were formerly in the same plane; that the shock of a comet, or some mighty revolution on the earth, gave the axis of our planet this inclination, and that, for thousands of years, the axis has been returning to its original position, which it will reach after 190,000 years. Laplace, on the contrary, in his *Mécanique Céleste*, showed that this could never take place, but that the decrease of the angle between the planes of the equator and the ecliptic depends merely upon a periodical effect, arising from the action of the other planets; that, after a certain time, it will increase again, and that the limits of variation are narrow and fixed. A very long space of time will be required to make satisfactory observations respecting this fact. The inclination of the ecliptic, or, which is the same thing, the inclination of the axis of the earth towards the ecliptic, is subject to another change, which makes it increase and decrease, alternately, for nine years, during which time the greatest difference amounts to 18″.

Eddies are irregular movements of water or of wind, or those deviations from the principal direction of the whole stream which are occasioned by obstacles of any kind. When these irregular motions become rotary or circular about a certain centre, they assume the title of whirlpools. (See Whirlpool and Whirlwind.)

Edulcoration; the process of freeing a difficultly soluble substance from one that is easily soluble, by means of distilled water. It differs little from lixiviation, except that the former term respects the insoluble residue, and the latter the soluble portion. Thus we say, to lixiviate wood ashes, because the object of the process is to procure the soluble alkaline ingredient separate from the earth and other impurities with which it is mixed; and, on the other hand, we say, to edulcorate the precipitate from alum, when the intention of the operation is to obtain the earth quite pure from soluble matter.

Effervescence, in *chemistry*, is a rapid disengagement of gas taking place within a liquid; in consequence of this numerous bubbles rise to the surface, forming a head of froth, and bursting with a hissing noise. There is some resemblance between effervescence and fermentation; the latter, although the source of the gas, in process is very different. Hence chemists formerly applied the term fermentation to all the phenomena which are at present denoted by effervescence. Gas produced by effervescence is by means of single or double elective affinity; in the one case it is generally carbonic acid gas, in the other it is either nitrous gas or hydrogen. Gas can have but little affinity with the fluid in which it is immersed, in order to produce effervescence. Thus, carbonic and muriatic acids are both gases, and are both extricated from alkaline combinations by sulphuric acid; yet a solution of carbonate of potash in water will produce a vehement effervescence with sulphuric acid, while muriate of potash in the same circumstances will occasion none at all, the carbonic acid having a very slight affinity for water acidulated by sulphuric acid, while the muriatic acid will combine with the same very readily.

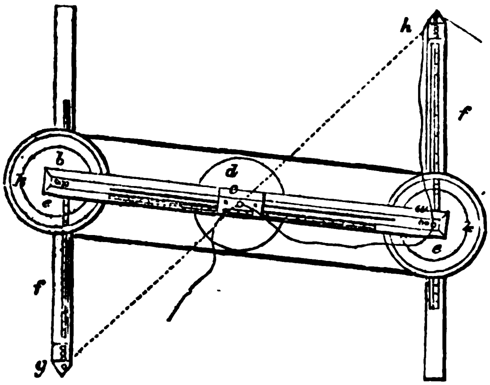
Efflorescent, in *chemistry*; a term applied to those crystals which, by parting with a portion of their water by exposure to air, crumble as though pulverized.

Eidograph. A very ingenious drawing instrument, under this title, has been invented by Professor Wallace, and described by Sir David Brewster. It is a fact well known, that artists of various descriptions, who have frequent occasion to imitate original designs, have long felt the want of a convenient mathematical instrument, by which a copy may be made with neatness and expedition, that shall have any given proportion to the original. The pantograph is the only instrument that has been successfully employed; but, although correct and plausible in theory, in practice it is found to be so very imperfect,

that the artist hardly ever thinks of making use of it.

A consideration of the essential service that would be rendered to the graphic art, by a copying instrument which should be at once simple in its theory and easy in its application, induced Mr. Wallace to turn his attention to the subject; and, in the summer of 1821, he produced a model of a copying instrument, which he has denominated an eidograph. The instrument, and its application to the copying of a very great variety of subjects, has been shown to engineers, engravers, and other competent judges in London and in Edinburgh, and their opinion of its utility has been such as to leave no doubt of its completely fulfilling the views of the inventor.

The instrument is represented in the accompanying figure.



The principal or central beam, which is made of mahogany, slides backward and forward in a socket in the centre; the socket turns on a vertical axis, supported by a fulcrum, which stands on a table. There is a slit in the beam, through which the axis of the socket passes, so that when the beam slides in the socket a portion of it passes on each side of the axis. There are two equal wheels, below the beam, which turn on axes that pass through pipes fixed at *a*, *b*, near its extremities; and a steel chain passes over the wheels as a band, by which a motion of rotation may be communicated from the one to the other. There are two arms, *f*, *f*, which slide in sockets along the lower face of the wheels, just under their centres: at the extemity, *g*, of one arm, there is a metal tracer, with a handle attached to it, by which its points may be carried over the lines in any design; and at *h*, the extremity of the other arm, there is a black-lead pencil fixed in a metal tube, which is ground to fit so exactly into a pipe as just to slide up or down. In using the instrument, the pencil in its tube is raised by a thread which passes over a pulley, and it descends again by a weight with which it is loaded.

From the perfect equality of the wheels, it is easy to see that, if the arms attached to them be placed parallel in any one position, they will retain their parallelism, although one of the wheels, and consequently both, be turned on their centres. Supposing, now, that *b*, *c*, and *a*, *c*, the parts into which the axis is divided at the centre, have any proportion whatever to each other, if the distances of the tracing point, *g*, and pencil point, *h*, from the centres of their wheels have the very same proportion, then it follows, from the elements of geometry, that the tracing point *g*, the centre *c*, and the pencil point *h*, will be in a straight line; and farther, that *c*, *g*, and *c*, *h*, the distance of these points from the centre, will have to each other the constant proportion of *c*, *b*, to *c*, *a*, or of *e*, *g*, to *a*, *h*. Such being the geometrical property of the eidograph, if any subject to be copied be fixed to the table on which the instrument stands, and the tracing point be carried over every line of the design, the pencil point will trace a copy in all respects similar to the original. To facilitate the adjustment of the instrument, so that the copy may have any given ratio to the original, there are scales of equal parts on the beam and the two arms. By these and verniers, both halves of the beam, and equal lengths on the arms, are each divided into one thousand equal parts, and at certain intervals corresponding numbers are marked on them. By means of the scales, when any ratio is assigned, the adjustment is made without the least difficulty.

To avoid any derangement by the chain slipping on the wheels, there are clamps provided, which hold it fast to the wheels at points where it never quits them. They are slackened when the instrument is adjusted.—*Scientific Gazette.*

Elain; the oily principle of fat, obtained by submitting fat to the action of boiling alcohol, allowing the stearin to crystallize, and then evaporating the alcoholic solution; or, by the simple process of pressing any oily or fatty substance between folds of bibulous paper, the oily matter or elain is absorbed, while the stearin remains. The paper being then soaked in water, and pressed, yields up the elain. It possesses much the appearance and properties of vegetable oil, is liquid at the temperature of 60° Fahr., and has an odour derived from the solid fat from which it has been extracted. It is readily soluble in alcohol, and forms soaps with alkalies; in doing which, however, it undergoes decomposition, and is converted, according to Chevreul, into a peculiar acid, called by him *oleic acid*, which combines with the alkali employed. This acid is obtained by submitting the soap formed by the action of potash on hog's lard to the action of boiling water; the solution, on cooling, deposits a sediment, consisting of the margarate of potash, while the oleate of potash remains in solution. The oleate of potash is decomposed by tartaric acid, again combined with potash, and again decomposed by tartaric acid, when the oleic acid rises to the top in the condition of an oily-like fluid. It is insoluble in water, soluble in alcohol, reddens litmus, and combines with the different salifiable bases, forming compounds somewhat analogous to soaps. At a temperature of 35° Fahr. it congeals into crystalline needles.

Elasticity; the peculiar property of bodies, by virtue of which the particles of which they are composed, when moved out of their positions by an external force, or pressed into a narrower space, tend to return to their former position, as soon as the external force ceases to act. A bow, bent by the tension of the string, recovers its previous form when the tension is relaxed.

Let an ivory ball fall upon a plate of marble, it is partially flattened by the impulse, but becomes immediately round again as soon as the force of the blow is destroyed. Here we see the cause of its rebounding from the hard surface. This property of elasticity is particularly observable in atmospheric

air. If it is enclosed in a vessel, and pressed with a piston, as soon as the force is removed from the piston, the air throws it up violently. This is the principle of the air-gun. There is an important difference between the elasticity of solids and fluids: the former tend to recover their previous form; the latter to expand into a greater space, whence the term *expansibility* is applied to them. For the sake of distinction, the elasticity of solid bodies may be termed attractive, and that of fluids expansive. The degree of it is very different in different bodies, and in many it is increased by art. Those bodies in which it cannot be perceived at all are called *unelastic*.

The elasticity of a solid body is greater the more its particles are expanded. If all the particles of a body are so far expanded that their elasticity is just equal to the expansive power, the expansion can be carried no farther without separating the particles. The weights necessary to produce a given degree of extension must be proportionate to the extension already existing. If three cords, of the same size and substance, stretched in proportion to the numbers 1, 2, 3, are to receive each a given amount of additional extension, the weights necessary to produce this extension are as 1, 2, 3.

The laws of elasticity in fluids are different from those in solids. In heavy elastic fluids, the inferior layers support the weight of the superior; in a cylindrical vessel, therefore, the bottom suffers the pressure of the whole mass of elastic fluid, and the lower strata are sensibly denser than the upper. A difference is made, too, between absolute and specific elasticity. By the former is understood the peculiar property of bodies to repel a pressing force, in itself, and without regard to temperature and density. This must be always equal to the pressing force. But, as different kinds of matter may press with equal force under unequal densities and temperatures, that is called specifically most elastic which with a less density presses with a force equally strong, and with an equal density stronger. In all elastic fluids, the specific elasticity increases with the temperature; it is likewise augmented by greater density: if air is confined, and made more dense, its specific elasticity is greater in proportion to its increase of density.

Elbow, in *anatomy*, is the joint formed between the *humerus*, *radius*, and *ulna*.

Elbow is also used by masons, architects, &c., for an obtuse angle of a wall, building, or road, which diverts it from its right line.

Elder; a name given to the different species of the genus *sambucus*. The uses of the elder are more numerous than those of most other shrubs. There is scarcely any part of it which has not been advantageously employed in some way or other. The wood is yellow, and in old trees becomes so hard that it will receive a polish almost as well as box, and indeed is often used as a substitute for box-wood. It is likewise employed by turners. Sir J. E. Smith has remarked that this tree is, as it were, a whole magazine of physic to rustic practitioners, and is not quite neglected even by professional men. Ointments have been made of the green inner bark, and of the leaves. The dried flowers, infused in water, are used in fomentations or as tea, and, mixed with buttermilk, have sometimes been used as a wash for the face. An infusion of the leaves is sometimes sprinkled by gardeners over the buds of such flowers as they wish to preserve from caterpillars. Elder flowers have an agreeable flavour, which they impart in distillation to water; they are likewise used to give a flavour to vinegar. The berries are poisonous to poultry, but their juice, properly fermented, makes a pleasant and wholesome wine, and in Germany a very pure and strong spirit is distilled from them. The juice of elder berries is sometimes employed to give a red colour to raisin or other sweet wines. The young shoots of this shrub are filled with an exceedingly light pith, which is cut into balls for electrical experiments, and is also made into toys for the amusement of children. The elder will thrive in almost any soil and situation; and every part of it has an unpleasant narcotic smell, which ought to render people cautious not to sleep under its shade, since, in such case, it might prove of serious injury to them.

Elecampane is a plant inhabiting the Eastern continent, and now naturalized and frequent in many parts of the United States, where it grows along roadsides, waste places, &c. This root possesses a bitter aromatic and somewhat acrimonious taste, and has been celebrated in disorders of the breast and lungs; it is useful to promote expectoration, and is also sudorific.

Electric Column, or aërial electroscope; an instrument composed of a great number of small circular and very thin plates (about the diameter of a sixpenny piece of silver) of paper and of zinc, alternately arranged, forming a column, the two ends of which are made to approximate, and at each of them is attached a small bell; a metallic clapper is then hung between them, and the whole apparatus is insulated by being fixed on glass stands. One end of the column is observed to become electrified plus, as it is termed, and the other minus; consequently, one of the bells becomes electrified plus or positive, and the other minus or negative: and the metallic clapper moving rapidly from one to the other, to equalize the two electricities, a pulsation is produced, and the bells ring. Neither the heat nor cold, dryness nor moisture, of the atmosphere, appears to have any considerable influence on the action of this instrument; but it is considerably altered by peculiarities in the electric state of the atmosphere. The prevalence of cirri ramifying about the sky in various directions, and accompanied often by other modifications, by dry, easterly, and changeable winds, and by numerous small meteors of an evening, which appear to indicate a disturbance in the atmospherical electricity, is found to be accompanied by an irregular action of the electric column.

Electrical Eel; a fish possessing the extraordinary property of communicating a sensation similar to an electrical shock, when touched with the hand, or an electric conductor. The seat of the organs which produce this curious effect is along the under side of the tail. They are composed of four bundles of parallel membraneous laminæ, placed very near each other, and nearly horizontally, extending from the skin to the central medial plane of the body, connected together by numerous vertical laminæ, arranged transversely. The little cells, or rather the small prismatic and transverse canals, intercepted by these two kinds of laminæ, are, according to Cuvier, filled with a gelatinous substance; and the whole apparatus is abundantly supplied with nerves.

Electrical eels are of several species, the most celebrated of which is the *gymnotus electricus*, found in the rivers of South America. It is said to possess power, when in full vigour, sufficient to knock down a man, and benumb the limb affected, in the most painful manner, for several hours after communicating the shock. By frequent use of this faculty it becomes impaired, and a considerable interval of rest is required to recruit its electrical properties. Through the medium of water, it is able to destroy small fishes at a considerable distance, directing the power at pleasure. Some authors aver that the *gymnotus* is found so large and powerful as to benumb a horse, and to drown men while bathing, by the violence of the shock.

A specimen of the *gymnotus*, which was conveyed alive to England some years since, afforded the curious an opportunity of verifying the reports of travellers as to its electric property. Since that period, numerous specimens have been examined, and the preceding observations confirmed. The property of communicating electrical shocks is common to some other fishes, of the same subdivision. Specimens of the *gymnotus electricus* are reported to attain the length of six or seven feet, but ordinarily they are about three and a half or four feet long. The flesh is eatable, and, in appearance and flavour, is said to resemble that of an eel.

Electricity; a branch of natural philosophy, which investigates the attractions and repulsions, the production of light, and the elevation of temperature, as well as the explosions and other phenomena attending the friction of vitreous, resinous, and metallic surfaces, and the heating, cooling, evaporation, and mutual contact of a great number of bodies. Its name is derived from the Greek word for *amber*, in which substance its phenomena were first observed. The knowledge which the ancients were possessed of, concerning this interesting and now very extensive branch of science, consisted in little more than the fact that amber acquired the power of attracting to itself light bodies, on being rubbed, ascribed by Thales, of Miletus, to an inherent soul or essence, which, awakened by friction, went forth, and brought back the light particles floating around.

In the year 1600, Dr. Gilbert, an English physician, published a treatise upon the magnet, in which he remarked that several other bodies besides amber can, by friction, be made to attract light bodies. The observations of Boyle, Otto Von Guericke, Newton, and a few other philosophers of the same period, contributed somewhat to the extension of our knowledge of electricity; but it was not before the middle of the 18th century, that the most important discoveries and generalizations of the phenomena before known upon this subject were made.

The order we shall adopt in the present article will be the following: 1. *A general statement of electrical phenomena, independent of all theory*. 2. *The theories which have been proposed for explaining these phenomena*. 3. *Electrical machines*. 4. *Effects of electrical attraction and repulsion*. 5. *Distribution of electricity*. 6. *Transference of electricity*. 7. *Laws of induction*. 8. *Motion of electricity*. 9. *Chemical effects of electricity*. 10. *Effects of electricity upon living bodies*. 11. *Electricity developed by changes of temperature and of form, from contact, compression, and other changes in bodies*. 12. *Electricity of the atmosphere*.

1. A dry glass rod, or a piece of amber or sealing-wax, when rubbed rapidly with a dry woollen cloth, and immediately presented to light bodies, such as fragments of paper, thread, cork, straw, cotton, or gold leaf, will first attract and then repel them. The bodies which have thus acquired this attractive and repulsive power are said to be excited. All substances, however, are not capable of being easily excited; hence the distinction of bodies into classes—electrics, and non-electrics.

The principal electric substances may be thus enumerated: amber, gum-lac, resin, sulphur, glass, the precious stones, silk, the fur of most quadrupeds, and almost all vegetable substances which have been thoroughly deprived of moisture, as baked wood, and dry paper. If the light bodies which have been repelled from an excited electric be again presented to it, they will, provided they have touched no other body, continue to be driven off. Some substances remain in contact with the electric longer than others; fibres of cotton adhere some time, while metallic bodies are repelled the instant after contact. Two bodies, which have both been in contact with the same electric, mutually repel each other.

If a glass tube of considerable diameter, and two or three feet in length, be employed for the experiment, we notice in a dark room, during the friction, flashes of light, of a bluish tinge, extending over every part of the tube; and sparks, attended with a sharp snapping sound, will be seen to dart out in every direction. If we present to it, after rubbing, a round metallic ball, sparks will be obtained as the ball approaches the tube; and, if the knuckle be presented instead of the ball, the same effect takes place, accompanied with a pricking sensation.

If a metallic ball be suspended in the air by silk, thread, or fibres of worsted or hair, or a rod of glas , and rubbed while in this situation by an electric, it will exhibit the same properties of attraction and repulsion as if it had been itself an electric. That the ball should thus be cut off from contact with any substance, except the air and the electric which sustains it, is essential to the success of the experiment.

Should an excited electric be placed near a light pith ball suspended by silk, the ball will, in the first place, approach the electric, but after contact will recede from it. If now, uncovering the electric, we present to the ball which has thus touched it a second ball, similarly suspended, but which has had no previous communication with any electric, we shall find that these two balls will attract one another, and come into immediate contact. The same results are repeated between this second ball and a third, which may be presented to it, and so on in succession, with a continued diminution, however, in the rapidity of the movements, indicative of a diminished power, in consequence, as it would seem, of its being distributed among a number of bodies.

From these facts we infer that the electric imparts to the balls, suspended as above, properties exactly similar to those which had been excited in itself by friction. By repeated contact with a number of bodies, an excited electric is found to lose its electrical powers, in the same degree as these powers have been acquired by the bodies themselves; and fresh excitation alone can renew them. It is evident, therefore, that electricity is capable of being transferred, in the same sense as caloric, of which we

speak as being communicable, and, like caloric, it is weakened by diffusion among a number of bodies. If an electrified ball be touched with the finger or by a rod of metal, it will be deprived of the whole of its electricity, which will pass to the finger or rod touching it; the ball being left in its original or natural state, and again becoming susceptible of being attracted, either by an excited electric, or by another body to which electricity has previously been communicated. If a rod of glass be applied, instead of the finger or metallic rod as above, the body touched remains unaffected, notwithstanding the contact.

We are thus led to conclude that some substances, such as glass, are incapable of conducting electricity; while others, such as metals, and the human body, readily conduct it. And it is found that all *electrics* are *non-conductors*, while, on the contrary, *conductors* are *non-electrics*. The permanence of electricity in metallic bodies, suspended in the air by silken threads, proves that the air, as well as silk, is a non-conductor, from which circumstance bodies surrounded by it, except on one side, and this side being in contact with a non-conductor, are said to be *insulated*. If this condition be not observed, that is, if a body be in contact with conducting substances which communicate with the earth, its electricity will escape through them to the earth, which may be regarded as the great reservoir both for the absorption and supply of this fluid.

The insulating power of the atmosphere depends upon its density and its dryness. In proportion as the air is rarefied by the removal of the superincumbent pressure, its power of confining electricity diminishes, till at length, when the rarefaction is very great, it opposes scarcely any resistance to the passage of electricity. The presence of moisture in the air also diminishes its insulating power.

Water is a good conductor of electricity; accordingly, any portion of it suspended in the air tends to carry off electricity from bodies charged with it, and which are immersed in such an atmosphere. Moisture also easily attaches itself to glass and other electrics, depriving them of the power of insulation. Hence we discover the reason why experiments which succeed in a clear, dry day, will often fail in damp weather, and the utility of drying all the instruments employed in electrical experiments, in order to exclude, as much as possible, the interference arising from the presence of condensed moisture.

The conducting powers of most bodies are influenced by changes of temperature, and also of form. Thus water, in its liquid state, is a good conductor; but when in the state of ice, at a temperature of 13° Fah., it is a non-conductor, and capable of being excited by friction like any other electric. Reducing substances to powder has an effect upon their powers of conducting electricity. Snow conducts less readily than ice at the same temperature; but glass, as well as sulphur, on the contrary, acquire some conducting power by being pulverized.

Vegetable and animal substances lose their conducting powers when made thoroughly dry. No substance with which we are acquainted can be said to be wholly impervious to electricity; nor, on the other hand, is there any body which opposes no resistance to the transmission of electricity.

The following table presents a view of the principal classes of bodies, arranged in a series, beginning with those possessed of the greatest conducting power, and terminating with those that have the least. The order in which they possess the power of insulating is, of course, the reverse of this:—

The perfect, or least oxidable metals.	Metallic ores.
The more oxidable metals.	Animal fluids.
Charcoal prepared from the harder woods, and recently ignited.	Water.
Plumbago.	Snow.
The concentrated mineral acids.	Living vegetables.
Dilute acids.	Living animals.
Solutions of metallic salts.	Smoke.
	Steam.
	Rarefied air.
	Earths and stones in their natural state.
	Pulverized glass.
	Flowers of sulphur.

———

Dry metallic oxides.	and other gases.
Oils.	White sugar.
Vegetable ashes.	Dry parchment.
Animal ashes.	Cotton.
Ice below 13° Fah.	Feathers.
Phosphorus.	Hair, especially that of a living cat.
Lime.	Silk.
Dry chalk.	Transparent gems.
Caoutchouc.	Diamond.
Camphor.	Glass.
Silicious and argillaceous stones, in proportion to their hardness.	Fat.
Porcelain.	Wax.
Baked wood.	Sulphur.
Dry atmospheric air,	Resins.
	Amber.
	Gum-lac.

Although the exact point in the above scale which forms the separation between conducting and insulating bodies cannot be precisely marked, yet we have indicated it by a division. The laws which regulate the gradual dissipation of electricity from imperfectly insulated bodies have been carefully investigated by M. Coulomb.

The causes which operate in these circumstances are, 1. the imperfection of the insulating property in the solids by which they are supported; 2. the contact of successive portions of air, every particle of which carries off a certain quantity of electricity; 3. the deposition of moisture upon the surface of the insulating bodies, which establishes communications between their opposite ends, and may be considered as virtually increasing the conducting power. Still another circumstance, which materially affects the dissipation of electricity, is the shape of the body in which it is accumulated. The form most favourable for its retention is that of a sphere; next, a cylinder terminated at both extremities by a hemisphere. On the other hand, electricity escapes most readily from bodies of a pointed figure, especially if the point projects to a distance from the surface. In such bodies, it is scarcely possible to retain any accumulation of the electric fluid; whereas pointed bodies receive electricity more readily than those of any other form.

Electric excitation in different bodies exhibits different phenomena. We have seen that light substances excited by glass repel one another, and are likewise repelled by the excited glass. The same thing also happens with respect to bodies which have re-

ceived their electricity from excited sulphur or sealing-wax. But, on examining the action of any of the bodies of the former class upon any of those belonging to the latter, we find that, instead of repelling, they attract each other; and, what is still more remarkable, the instant these bodies come in contact, provided they have both been electrified in an equal degree, they cease at once to exhibit any signs of electrical excitement, the electricity in the one appearing to neutralize that in the other.

Thus we seem to have evidence of two kinds of electricity; and as these were first noticed, the one in glass and the other in resinous bodies, they were named *vitreous* and *resinous* electricity. Their mode of action on matter has been expressed by the following general law, viz.: *Bodies charged with either species of electricity repel bodies charged with the same species, but attract bodies charged with the other species; and, at equal distances, the attractive power in the one case is exactly equal to the repulsive power in the other.* Accordingly, we learn the kind of electricity with which a given body is charged, by approaching it to an insulated pith ball, which has previously been touched either with excited glass, or with excited sealing-wax It is known, moreover, that, when two electrics are rubbed against one another, the one acquires, always, one kind of electricity, the other the opposite; and both are produced in equal degrees. Thus, when glass is rubbed by silk or flannel, just as much resinous electricity is produced by the silk or flannel as there is vitreous electricity produced in the glass; and consequently, as they are endowed with opposite electricities, there should be an attraction existing between the excited surfaces of the bodies rubbed.

The above fact is easily proved by the simple and familiar experiment of the ribbons. If a white and black ribbon, of two or three feet long, and perfectly dry, be applied to each other by their smooth surfaces, and then drawn repeatedly between the finger and thumb, so as to rub against each other, they will be found to adhere together, and, if pulled asunder at one end, will rush together with great quickness; while united, they exhibit no sign of electricity, because the operation of the one is just the reverse of that of the other, and their power is neutralized and inoperative. If completely separated, however, each will manifest a strong electrical power, the one attracting those bodies which the other repels.

The causes that determine the species of electricity excited, in the respective bodies of which the surfaces are made to rub against each other, have not been satisfactorily ascertained. The mechanical configuration of the surfaces appears to have more influence on the result than the nature of the substances themselves. Thus smooth glass acquires vitreous electricity by friction with almost every substance, except the back of a cat, which induces the resinous electricity; but roughened glass, if rubbed with the same substances, becomes chargeable with resinous electricity, while the rubbing bodies acquire the vitreous. Silk, rubbed by resin, takes the vitreous, but polished glass the resinous electricity.

The following is a list of several substances which acquire vitreous electricity when rubbed with any of those which follow them, in the order in which they are set down; and resinous electricity, if rubbed with any of those which precede :—

The back of a cat.	Paper.
Polished glass.	Silk.
Woollen cloth.	Gum-lac.
Feathers.	Roughened glass.
Wood.	

In the experiment above mentioned of the silk ribbons, the black ribbon exhibited the vitreous and the white one the resinous electricity. But when the ribbons are differently excited, as the one being drawn lengthwise and at right angles over a part of the other, the one which has suffered friction in its whole length acquires vitreous, and the other resinous electricity. Indeed the slightest difference in the conditions of these and similar experiments, or the species of electricity arising from friction, will be often sufficient to produce opposite results.

Another important observation, with regard to electrical phenomena, requires to be stated previously to our conclusion of the present head. Whenever a body is charged with electricity, although it be perfectly insulated, it tends to produce an opposite electrical state in all the bodies in its vicinity, and this with greater energy in proportion as the distance is smaller. This effect is termed the *induction* of electricity. In consequence of this law, if an electrified body, charged with either species of electricity, be presented to an unelectrified or neutral body, the electrical condition of the different parts of the neutral body is disturbed. The electrified body induces a state of electricity contrary to its own in that part of the neutral body which is nearest to it, and consequently a state of electricity similar to its own in the remote part. Hence, the neutrality of the second body is destroyed by the action of the first; and the adjacent parts of the two bodies, having now opposite electricities, will attract each other. It thus appears that the attraction which is observed to take place between electrified bodies and those that are unelectrified is merely a consequence of the altered state of those bodies, resulting directly from the law of induction.

II. The hypothesis which naturally suggests itself for the explanation of the phenomena above stated is that of a very subtle, imponderable, and highly elastic fluid, pervading all natural bodies, and capable of moving with various degrees of facility through the pores or actual substance of different kinds of matter. In some, as in those we call *conductors* or *non-electrics*, it moves without any apparent obstructions; while in others, as in those we call *non-conductors* or *electrics*, it moves with difficulty.

As the phenomena appear to indicate the agency of two kinds of fluid, we shall, for the present, assume the existence of two species, and shall speak of these under the names of the *vitreous* and the *resinous electricities*. They must each have, when separate, the same general properties as have already been enumerated above; while, in relation to each other, there must be a complete contrariety in their nature, so that, when combined together, their action on the bodies in their immediate vicinity shall cease. And it is when existing in this state of union or neutrality that bodies are said to be in their natural state as respects electricity. We shall now proceed to compare the suppositions we have made with the facts, as presented to us by nature, and developed by experiment.

Facts connected with *excitation*. From various

causes (of which the friction of surfaces is one), the state of union in which the two electricities exist in bodies, is disturbed: the vitreous electricity is impelled in one direction, while the resinous is transferred to the opposite; and each manifests its peculiar powers. When accumulated in any body, each fluid acts in proportion to its relative quantity, that is, to the quantity which is in excess, above that which is still retained, in a state of inactivity, by its union with electricity of the opposite kind. Thus, when glass is rubbed with a metallic amalgam, a portion only of the electricities at the two surfaces is decomposed: the vitreous electricity resulting from this decomposition attaches itself to the glass; the resinous to the amalgam. What remains in each surface undecomposed, continues to be quite inert.

Facts connected with *distribution*. Both of these fluids being highly elastic, their particles repel one another with a force which increases in proportion as their distance is less; and this force acts at all distances, and is not impeded by the interposition of bodies of any kind, provided they are not themselves in an active electrical state. It has been deduced from the most careful analysis that this force follows the same law with that of gravitation: viz. that its intensity is inversely as the square of the distance.

The mode in which the electricity imparted to a conducting body, or to a system of conductors, is distributed among their different parts, is in exact conformity to the results of this law, as declared by mathematical investigation. While the particles of each fluid repel those of the same kind, they exert an equally strong attraction for the particles of the other species of electric fluid. This attraction, in like manner, increases with a diminution of distance, and follows the same law as to its intensity: viz. that of the inverse ratio of the square of the distance. This force, also, is not affected by the presence of any intervening body.

Facts connected with *transferrence*. Since the two electricities have this powerful attraction for each other, they would always flow towards one another, and coalesce, were it not for the obstacles thrown in their way by non-conductors. When, instead of these, conducting substances are interposed, they enter into union with great velocity, producing, in their transit and confluence, several remarkable effects.—When once united, their powers remain dormant, until again called into action by the renewed separation of the fluids.

Facts relating to *attraction and repulsion*. The repulsion which is observed to take place between bodies that are insulated, and charged with any one species of electricity, and other bodies similarly charged, is derived from the repulsive power which the particles of this fluid exert towards those of their own species; and the attractions between bodies differently electrified is derived from the attractive power of the vitreous particles for those of the opposite kind. In all cases the movements of electrified bodies represent the forces themselves which actuate the particles of the developed electricities they contain.

Facts relating to *induction*. Wherever one of the electricities exists in an active state, it must repel all the particles of the same electricity in all surrounding bodies, and attract those of the opposite species. Thus the law of induction is seen to be a direct consequence of the hypothesis we are considering.

Thus far we have proceeded upon the hypothesis of two distinct electric fluids. It was, however, discovered by Franklin that it is equally easy to account for these phenomena, on the supposition of their resulting from the agency of a single electric fluid. This theory supposes that the single agent in question, and which we shall call the *electric fluid*, is highly elastic, or repulsive of its own particles,—the repulsion taking place with a force varying inversely as the square of the distance; that its particles attract and are attracted by the particles of all other matter, following the same law of the inverse square of the distance; that this fluid is dispersed through the pores of bodies, and moves through them with various degrees of facility, according as they are conductors or non-conductors.

Bodies are said to be in their natural state, with regard to this fluid, when the repulsion of the fluid they contain of a particle of fluid at a distance is exactly balanced by the attraction of the matter in the body for the same particle; and, under these circumstances, they exhibit no electrical phenomena. But if subjected to certain operations, as friction, the equilibrium is destroyed, and they acquire more or less than when in their natural state. Whenever they acquire a quantity of fluid greater than in their natural state, they are said to be *positively* electrified, or electrified *plus*, and present the phenomena ascribed to what was called *vitreous* electricity. When, on the other hand, there is a quantity less than what is required in order to be in their natural state, they are said to be *negatively* electrified, or to be electrified *minus*, in which case they correspond with the state of resinous electricity.

The state of positive electricity, then, consists in a redundance of the electric fluid, or in matter over-saturated with this fluid; that of negative electricity, in a deficiency of fluid, or in matter under-saturated, or, what may be considered the same thing, in redundant matter. In considering the mutual electrical actions of bodies, the portions in which the matter and the fluid mutually saturate each other need not be taken into account, since their actions, as we have seen, are perfectly neutralized; and we need only attend to those of the redundant fluid and the redundant matter.

When a body contains more than its natural proportion of electric fluid, the surplus will, by the repulsive tendency of its particles, overflow and escape, unless prevented by insulation, until the body is reduced to its neutral state.

When under-saturated, the redundant matter will attract fluid from all quarters from which it can receive, until it is again brought to its natural state. The mutual recession of two positively electrified bodies is a direct consequence of the redundance of the electric fluid contained in each, this fluid being attracted to the matter by its attraction for it in both bodies; and, the fluid in one being repulsive of the fluid in the other, the bodies are necessarily impelled in the direction of the repulsion. In the same manner, the mutual attraction between two bodies, one of which is electrified plus and the other minus, is the immediate effect of the attraction of the redundant fluid in one for the redundant matter in the other, and *vice versâ;* for this attraction is mutual.

The mutual recession of two bodies, negatively electrified, does not appear to be accounted for upon the Franklinian theory. In order to do this, therefore,

it has been found necessary to append to it the following provision; that particles of simple matter, or bodies unsaturated with the electric fluid, are mutually repulsive. Without this provision, indeed, we are unable to explain the want of action between two neutral bodies; for, the repulsion of the fluids in both bodies being balanced by the attraction of the fluid in the one for the matter in the other, the remaining attraction of the fluid in the second body for the matter in the first would be uncompensated by any repulsion, and the forces would not be held in equilibrium, as we find they really are.

The law of electrical induction is an immediate consequence of the Franklinian theory. When a body charged with electricity is presented to a neutral body the redundant fluid of the former exerts a repulsive action on the fluid of the latter body; and, if this happens to be a conductor, it impels a certain portion of that fluid to the remote end of this body, which becomes at that part positively electrified; while its nearer end, which the same fluid has quitted, is consequently in the state of negative electricity. If the first body had been negatively electrified, its unsaturated matter would have exerted an attractive force on the fluid in the second body, and would have drawn it nearer to itself, producing an accumulation or redundance of fluid at the adjacent end, and a corresponding deficiency at the remote end; that is, the former would have been rendered positive, and the latter negative. All this is exactly conformable to observation.

The facts with regard to transference are easily explicable upon this hypothesis, and they arise from the destruction of the equilibrium of forces, which confined the fluid to a particular situation or mode of distribution. Indeed, there is hardly any fact that is explained on the hypothesis of two fluids which is not equally explicable on the Franklinian theory; and the explanations by the first are easily converted into those of the second by substituting the expressions of *positive* and *negative* for those of *vitreous* and *resinous electricities*. The principal advantage of Franklin's system is its superior simplicity. When viewed as a mere hypothesis, calculated to facilitate our comprehension of the phenomena and of their connections, it is a matter of indifference which we employ, since they will either of them answer the purpose. For the future, however, we shall more generally employ the Franklinian theory, on account of its greater convenience.

III. *Electrical Machines.* The essential parts of an instrument for procuring large supplies of electricity, for the purposes of experiment, are the electric, the rubber, the prime conductor, the insulator, and the machinery for setting the electric in motion. The electric, by the excitation of which the electricity is to be developed, may be made of various substances. Polished glass has, however, received the preference. Its form is that of a hollow cylinder, or of a flat circular plate, revolving upon a horizontal axis. The cushion is usually made of soft leather, generally basil skin, stuffed with hair or wool, so as to be as hard as the bottom of a chair, but yet sufficiently yielding to accommodate itself, without much pressure, to the surface of the glass to which it is applied The prime conductor is a cylindrical tube, each end terminating in a hemisphere. There is no advantage in its being made solid, for the electricity is only contained at the surfaces. It may be made of thin sheet brass, or copper, or tin, or of pasteboard covered with gold leaf or tin-foil. Care must be taken that its surface be free from all points and asperities; and the perforations which are made in it, and which should be about the size of a quill, for the purpose of attaching wires and other kinds of fixtures, should have their edges well rounded and smoothed off. In order to render the arrangement of these parts more intelligible, we will describe one of the simplest and best of the cylindric machines. The glass cylinder *a b*, *Fig.* 4, Plate I. *Electricity*, is from 8 to 16 inches in diameter, and from 1 to 2 feet long, supported, for the purpose of insulation, on two upright pillars of glass, which are fixed to a firm wooden stand. Two hollow metallic conductors, equal in length to the cylinder, and about one-fourth of its diameter, are placed parallel to it, one on each side, upon two insulating pillars of glass, which are cemented into two separate pieces of wood, that slide across the base so as to allow of their being brought within different distances from the cylinder. To one of these conductors the cushion is attached, which is of the same length with the conductor *c*. Its pressure against the cylinder is regulated by an adjusting screw adapted to the wooden base at *e*, on which the glass pillar that supports the conductor is fixed. From the upper edge of the cushion there proceeds a flap of thin oiled silk, *d*, which is sewed on the cushion about a quarter of an inch from its upper edge. It extends over the upper surface of the glass cylinder to within an inch of a row of metallic points, proceeding, like the teeth of a rake, from a horizontal rod, which is fixed to the adjacent side of the opposite conductor. The motion of the cylinder, which is given by a single handle or by a multiplying wheel, must always be given in the direction of the silk flap.

That part of the cushion which comes in contact with the glass cylinder should be coated with an amalgam of tin, zinc, and mercury, applied by means of hog's lard. The amalgam should be placed uniformly over the cushion, until level with the line formed by the seam which joins the silk flap to the face of the cushion. No amalgam should be placed over this line, nor on the silk flap; and it is even requisite to wipe the silk flap clean whenever the continued motion of the machine shall have soiled it by depositing dust or amalgam on its surface.

The best amalgam is formed by melting together one ounce of tin and two ounces of zinc, which are to be mixed, while fluid, with six ounces of mercury, and agitated in an iron or thick wooden box until cold. It is then to be reduced to very fine powder in a mortar, and mixed with a sufficient quantity of hog's lard to form it into a paste.

The mode in which the electrical machine just described acts will readily be understood. The friction of the cushion against the glass cylinder produces a transfer of electric fluid from the former to the latter; that is, the cushion becomes negatively and the glass positively electrified. The fluid, which thus adheres to the glass, is carried round by the revolution of the cylinder, and its escape is at first prevented by the silk flap which covers the cylinder, until it comes to the immediate vicinity of the metallic points, which, being placed at a small distance from the cylinder, absorb nearly the whole of the electricity as it passes near them, and transfers it to the prime conductor. Positive electricity is thus accumulated in the prime conductor, while the conductor connected with the

London. Published by William Orr, Paternoster Row, May 20th 1833.

cushion, being deprived of this electricity, is negatively electrified, and light balls suspended by threads at *f* being oppositely electrified will attract each other. If both these conductors are insulated, this action will soon have reached its limit; for, when the cushion and its conductor have been exhausted of their fluid to a certain degree, they cannot, by the same force of excitation, supply any further quantity to the glass. In order to enable it to do so, we must replenish it, or restore to it a quantity equal to what it has lost. This is done by destroying the insulation of the cushion through the means of a metallic chain or wire, extending from it to the earth, which is the great reservoir of the electric fluid. The prime conductor will now be supplied with a constant stream of positive electricity. If it be our object, on the other hand, to accumulate negative electricity by the same instrument, we have only to insulate the conductor to which the cushion is attached, and to connect the prime conductor with the ground, in order to allow the fluid to escape from it as soon as it is collected from the cylinder. The fluid will thus continue to be drawn, without interruption, from the negative conductor, as it now meets with no impediment to its discharge on the opposite side of the machine.

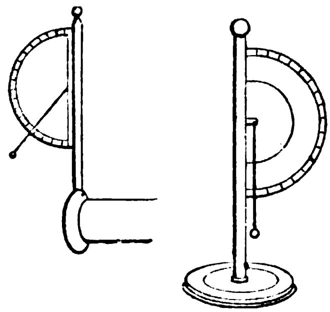
That the quantity of positive electricity produced in one conductor is exactly equal to that of the negative electricity in the other is proved by the fact, that, if the two conductors are connected by a wire, no signs of electricity are obtained in any of the conductors on turning the machine.

A person standing on a stool with glass legs is thereby insulated; and if, in this situation, he touch the prime conductor, either with his hand or through the medium of a metallic rod or chain, he may be considered as forming part of the same system of conductors. When the machine is worked, therefore, he will partake, with the conductor, of its charge of electricity, and sparks may be drawn from any part of his body by the knuckle of any other person who is in communication with the ground.

IV. The effect of electrical attraction and repulsion may now be exhibited much more distinctly with the aid of those considerable accumulations of electricity which we are enabled to form by the electrical machine. A pith ball, or a fragment of gold leaf, is very strongly and immediately attracted by the electrified conductor; and, the instant after it has come into contact with it, it is repelled; but it is now attracted by the other bodies in its neighbourhood, to which it communicates its own electricity, and then is again in a state to be influenced by the conductor, and to be again attracted; and this alternation of effects will continue as long as the conductor remains charged. This alternation of attractions and repulsions accompanying the transferring electricity by movable conductors is also illustrated by the motions of a ball suspended by a silk thread, and placed between two bells, of which the one is electrified and the other communicates with the ground. The alternate motion of the ball between the two bells will keep up a continual ringing. This amusing experiment has been applied to give notice of changes taking place in the electrical state of the atmosphere.

The mutual repulsion of bodies that are similarly electrified gives rise to many interesting experiments. A small figure in the shape of a human head, covered with hair, when placed upon the conductor and electrified, will exhibit the appearance of terror from the bristling up and divergence of the hair.

Advantage is taken of the repulsive property of electrified bodies for the construction of an instrument adapted to measure the intensity of the electricity they may contain. This instrument is called an *electrometer*. That invented by Henley consists of a slender rod of very light wood, serving as an index, terminated by a small pith ball, and suspended from the upper part of a stem of wood, which is fitted to a hole in the upper surface of the conductor. An ivory semicircle or quadrant is affixed to the stem, having its centre coinciding with the axis of motion of the rod, for the purpose of measuring the angle of deviation from the perpendicular, which the repulsion of the ball from the stem produces in the movable rod. The number of degrees which is described by the index affords some evidence of the quantity of electricity with which the apparatus is charged, though the instrument cannot be viewed as affording an exact measure of its intensity. Two of these are shown in the accompanying engraving; the first on the prime conductor of the machine, the other on a stand.



The *gold leaf electrometer* of Bennet, or rather *electroscope*, is a very delicate instrument, and is much employed for detecting the presence of electricity. It consists of two narrow slips of gold leaf, suspended parallel to each other in a glass cylinder (which secures them from disturbance by the air), and attached to the end of a small metallic tube, terminating above either in a flat surface of metal or a metallic ball. Two slips of tin-foil are pasted to the inside of the cylinder, on opposite sides, in a vertical position, and so placed as that the gold leaves may come in contact with these, when their mutual repulsion is sufficiently powerful to make them diverge to that extent. These slips of tin-foil terminate in the foot of the instrument, and thus are in communication with the earth. A very minute charge of electricity, communicated to the upper end of the tube, is immediately transmitted to the gold leaves, which are thus made to repel each other; but, if the repulsion is such as to make them strike against the tin-foil, their insulation ceases, and their electricity is carried off, and, becoming neutral, they resume their original position. We may here notice the electrometer invented by Coulomb, and called by him the *torsion balance*. It consists of a cylindrical glass jar, covered at the top by a circular glass plate, with a hole in its centre, through which descends, nearly to the bottom of the jar, a single fibre of the web of the silk-worm, with a needle of gum-lac or a piece of straw coated by sealing-wax, affixed to its lower extremity. The needle is terminated at one end by a small pith ball, and at the other by a disc of varnished paper, to serve as a counterpoise to the ball. The upper end of the silk fibre is attached to a kind of button, having a small index, and capable of

being turned round upon a circular plate divided into degrees. One side of the jar is perforated towards its bottom, to allow of the insertion of a short, horizontal bar, having a small metallic sphere at each of its ends, the one being within and the other upon the outside of the jar, and the former being so situated as just to allow the ball of the suspended needle to come in contact with it in the course of its revolution. By turning the button, or the index, the needle may be brought into this or any other required position with regard to the ball.

It is found by experiment that the angle of torsion of the silk fibre is, within a certain range of distance, very nearly in the direct ratio of the force which acts in producing the torsion; and therefore, if the two balls be placed in contact by turning the button, and then similarly electrified, the distance to which they are repelled by the angular motion of the suspended ball affords a measure of the repulsive force exerted. In like manner, the distance which the suspended ball is made to move, when it is attracted by the fixed ball, when the two have opposite electricities, gives accurate measures of the attractive forces.

V. It had long been observed that the quantity of electricity which bodies are capable of receiving does not follow the proportion of their bulk, but depends chiefly upon the extent of their surface. It was found, for example, that a metallic conductor, in the form of a globe or cylinder, contains just as much electricity when hollow as it does when solid, from which it was inferred that electricity does not extend throughout the mass of a body, but resides altogether at its surface. By the application of mathematical calculations to the theory, the most exact information with regard to the distribution of the electric fluid in bodies of different shapes has been obtained; and whenever a comparison has been instituted, even in cases of the most complicated kind, between the results of experiment and of theory, the most perfect agreement has been observed between them.

For the purpose of measuring the proportional quantities of electricity, with which different parts of the same or of different bodies are charged, no instrument is so well fitted as the balance of Coulomb. Such is its extreme sensibility, that a force only equal to the 270th of a grain is sufficient to make the needle perform an entire revolution; the 360th part of this force, therefore, or less than the 100,000th of a grain, is capable of being estimated by each degree of its angular motion.

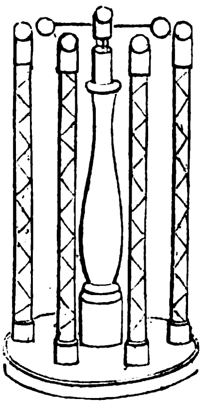
It would be inconsistent with the limits of the present article to go into a detail of the delicate methods of research adopted in the investigation of this subject. The following are among some of the most interesting results deduced from them. In a solid body, having the form of a perfect sphere, and charged with positive electricity, the whole of the fluid is, in consequence of the repulsion of its own particles, which is every where directed from the centre outwards, accumulated in a thin stratum, at the very surface of the sphere. If the body be charged with negative electricity, the deficiency of fluid will take place only in the superficial stratum of matter. If, instead of being spherical, the body have any other form, the electricity will be chiefly confined to the surface; and, if it have an elongated form, there will be a greater charge in the remoter parts than in those nearer to the middle.

This result of theory, respecting the limitation of electricity to the mere surface, is confirmed, in the most decisive manner, by the experiments of Coulomb. A conducting body, of a spheroidal shape, with small pits in various parts of its surface, half an inch in diameter, and one-tenth of an inch in depth, was electrified, and examined by the torsion balance. The bottoms of these pits afforded no indications of having received any electricity, while the even surface exhibited strong electrical excitement. We may conclude, both from theory and experiment, therefore, that although, strictly speaking, the electricity must reside within the substance of conducting bodies, it extends, in fact, to a depth so small as to be inappreciable by any known methods of observation.

The effect of an expansion of surface in lessening the intensity of electricity, while its absolute quantity remains the same, is illustrated by the following experiment: around an insulated cylinder, movable on an horizontal axis, and turned by an insulating handle, is wound a thin lamina of any metal, the end of which is semi circular, and has attached to it a silk thread. The whole apparatus communicates with an electrometer, formed of two linen threads, each terminating in a pith ball. On communicating a charge of electricity to the cylinder, the threads and balls of the electrometer attached to it diverge. Upon taking hold of the silk thread, and unrolling the metallic lamina from the cylinder, the balls gradually collapse, thus indicating a diminution in the intensity of electrical repulsion. But, on winding up the lamina, by turning the insulating handle, the electricity is restored, and the balls diverge to the same extent as before, allowance being made for the small dissipation of electricity, from the contact of the air during the experiment.

In the case of a long and slender lamina of conducting matter, charged with electricity, Coulomb found that its intensity continued nearly uniform, from the middle of the lamina to within a short distance from the ends; at that part it rapidly increased; and, at the very extremity, it became twice as much as at the middle part. He also found that in a cylinder 30 inches long, and 2 in diameter, the intensity of the electricity at the ends was to its intensity in the middle, or at any part more than 2 inches from the extremity, as 23 to 1. From which instances we infer that, if a conducting substance be drawn out into a point, the intensity of the electricity at that point will be exceedingly great, and that the point will accordingly absorb and draw into itself nearly the whole of the electricity that is contained in the body. This great concentration of electricity is found actually to take place in all points that project beyond the general surface. The pressure excited by the electric fluid against a non-conducting medium, such as the air, which opposes an obstacle to its escape, is in a ratio compounded of the repulsive force of its own particles at the surface of the stratum of fluid, and of the thickness of that stratum; but, as one of these elements is always proportional to the other, the total pressure must, in every point, be proportional to the square of the thickness. If this pressure be less than the resistance, or *coercive force* as it has been called, of the air, the electricity is retained; but, the moment it exceeds that force in any one point, the electricity suddenly escapes, just as a fluid confined in a vessel would rush out, if it were to burst open a hole in the side of a vessel.

The irruption of the electric fluid is marked by several very striking phenomena. A sharp snap is heard, accompanied by a vivid spark, and there are evidences of an intense heat being evolved in the line which the electricity takes. Its passage through a perfect conductor is unattended with light. Light appears only where there are obstacles in its path, by the interposition of imperfect conductors; and such is the velocity with which it is transmitted that the sparks appear to take place at the very same instant along the whole line of its course. Thus, if a row of small fragments of tin-foil be pasted, so as to be nearly in contact, on a piece of glass, and electricity be sent through them, by connecting one of its ends with the conductor of an electrical machine while the other end communicates with the ground, it will not be possible to detect any difference of time in the occurrence of the light in the different parts. If the tin-foil be arranged so as to represent a chain, it will appear luminous at each link, while conveying a charge of electricity.



A mode of showing a very beautiful electrical experiment is exhibited in the accompanying apparatus. It consists of a series of glass tubes, and a revolving wire with two knobs; and these, being made to rotate, give a series of sparks to the tinfoil on the different tubes, which thus become luminous.

The longest and most vivid sparks are obtained between two conductors having a rounded form, as may be exemplified in a common electrical machine, by presenting a metallic ball to that side of the prime conductor which is furthest from the cylinder of the machine; a spark is immediately seen, of considerable length, resembling a long streak of fire, extending from the conductor to the ball. Often, when the spark is very long, it is seen to have an angular or zigzag course, exactly like that of a flash of lightning. This irregularity is probably occasioned by the fluid darting obliquely in its course to minute conducting particles, as those of moisture, that are floating in the air, a little removed from the direct line of passage. Electrical light differs but little from the light obtained from other sources. Its brilliancy depends upon its real intensity. This fact has lately been proved by Mr. Wheatstone. When dry wood is employed, it appears in the form of faint red streams; but metals afford a light of greater brilliancy. Its colour is subject to variations from a great number of different circumstances. Sparks passed through balls of wood or ivory are of a crimson colour; but this depends upon their position with regard to the surface.

Electric sparks, passing from one polished metallic surface to another, are white; but, if the finger be presented to an electrified conductor, the sparks obtained are violet. They are green when taken from the surface of silvered leather; yellow when taken from finely powdered charcoal; and of a purple colour when taken from the greater number of imperfect conductors.

In exceedingly rarefied air, the colour of the spark is green; in denser air, it acquires a blue tint, and passes to a violet and purple as the condensation of the air is increased. In making these experiments, it is found that in proportion as the medium is more rare its conducting power increases, and a smaller intensity of electricity is required for the production of light. In the ordinary vacuum of the air-pump, the passage of electricity is rendered sensible by streams or columns of diffused light occasionally varying in their breadth and intensity, and exhibiting movements which give them a marked resemblance to the coruscations of the aurora borealis.

It was at first imagined that the light which appears during the passage of electricity was actually the electric fluid itself, become luminous from its high degree of accumulation. But, since we know that common atmospheric air becomes luminous by violent compression, and we must also presume that electricity exerts a very sudden and powerful pressure upon the air by its passage through that resisting medium, we are certainly justified in drawing the inference that the same phenomena proceed, in both cases, from the same cause. The sound which accompanies the various modes of transference is subject to modifications dependent upon the degree and suddenness of the impulses given to the air. The full, short, and undivided spark is attended with a loud explosion; the more lengthened spark with a sharper snap, which becomes more broken and rattling in proportion to the distance it has to traverse.

The great increase of intensity which the electric fluid acquires at the extremities of all elongated conducting bodies, and especially the indefinite augmentation of this intensity at the apex of all projecting points, has been alluded to above. This intensity will necessarily be accompanied with a powerful disposition in the fluid to escape—a circumstance which furnishes a natural and exact explanation of the rapid dissipation of electricity which takes place from all bodies of a slender and pointed form.

The illustration of these positions is seen in bringing metallic rods of different forms near the prime conductor of a machine charged with either species of electricity, the conductor being furnished with a pair of pith balls, suspended by a fine wire, whose divergence indicates the presence and degree of the electricity in the conductor: if the metallic rod have a bell at the end which is brought near the charged conductor, the pith balls will be but slightly affected; whereas, if it terminate in a sharp point, and the point be presented to the conductor at the same distance as the ball was in the former case, the divergence of the balls will immediately cease, showing that the electrical charge has wholly disappeared.

Currents of air always accompany the discharge of electricity from pointed bodies; for each particle of air, as soon as it has received its electricity from the point, is immediately repelled by the body. Many amusing experiments are founded on this principle. Let two cross wires, bent at right angles near the ends, which terminate in points, and pointing in a similar direction with respect to the axis, be supported at their centre upon a fine point, and electrified by being placed upon the prime conductor of a machine; each of the points will give off a stream of electricity, and the wires will revolve backward with considerable rapidity. An apparatus consisting of wires terminating in points, and having balls annexed to them, to represent the planets, may be constructed so as to re-

volve when electrified, and thus to imitate the planetary motions. Such an apparatus has been called an *electrical orrery*, and is shown in *Plate* 2, ELECTRICITY.

When the transfer of electricity takes place between smooth surfaces of a certain extent, no difference can be perceived in the nature and appearance of the spark, whichever be the position of the negative surface. But, in the passage of electricity through points, the effect is considerably modified by the species of electricity with which the bodies are charged; or, in other words, by the direction in which the fluid moves. When the electric fluid is escaping out of a pointed conductor, the luminous appearance is that of diverging streams, forming what is termed a *pencil of light*, and resembling the filaments of a brush. When, on the contrary, the electric fluid is entering into the pointed body, the light is much more concentrated at the point itself, having a resemblance to a star, in which if any streams appear they are disposed like radii, and equally so in all directions. This difference in these two appearances may be employed, on many occasions, as a useful criterion of the species of electricity, at least, which is passing from one conductor to another, if not of the absolute direction of its motion. For, if a needle be presented to an electrified body, the appearance of a star on the needle will show that the electricity of that body is positive; while, on the contrary, a luminous brush on the needle will indicate that the body is negative.

These observations seem to indicate the emanation of some material fluid from the positive and its reception by the negative point. It has, accordingly, been urged as an argument in favour of the Franklinian theory. The diverging lines on one side, and their inflections on the other, represent exactly the paths of particles flowing out as from a pipe, and urged forward by a force which gives them such a projectile velocity as to prevent their spreading out beyond a certain distance from the direct line of projection. But this very velocity will carry the particles that happen to have deviated most somewhat beyond the point to which they are attracted; while the attraction to this latter point will tend to deflect them from the line of their path, and gradually turn them back, so that they will arrive at the point of attraction by very different paths, and some even by a retrograde motion. Hence, while, in the former case, they form a diverging cone of rays, in the latter they must be distributed on all sides of the point, like the rays of a star.

VI. Active electricity, existing in any substance, tends always to induce the opposite electrical state in the bodies that are near it. Now, it is impossible to induce one electrical state in any body without, at the same time, producing the opposite state in the same body, or in the one which is immediately contiguous. It follows, therefore, that if the bodies subjected to the inductive influence are non-conductors, although the tendency to produce the opposite electricity exists, yet, in consequence of the immobility of the fluid, it can produce no visible change.

In proportion as the body opposes less resistance to the passage of electricity, the operation of the disturbing force becomes sensible. For example, in the case of a positively charged electric, acting by induction on an insulated conducting body, the redundant fluid in the former must tend to repel all the fluid contained in the latter; a portion of this fluid must, therefore, be driven from the side adjacent to the first body, towards the remoter side. The adjacent side will thus be rendered negative; the remoter side positive. But this will take place to a certain extent only; for there is a limit at which the repulsion of the fluid accumulated at the remote end will just balance the repulsion of the fluid in the electric, added to the attraction of the under-saturated matter, in the near end; and, when the limit has been attained, the flow of electric fluid from the near to the remote end of the body will cease, and an equilibrium will be established. Experiment fully confirms this theory, as may be seen by bringing a cylinder of metal of some length, with rounded ends, near an electrified globe of glass, taking care that it be not sufficiently near to receive any quantity of electricity by transference.

By means of the electrometer of Coulomb, we perceive that the part of the conductor nearest to the electric is negative, and the part most remote is positive; while, about the middle of the cylinder, the body is in a neutral state. The electricity is found to diminish as we proceed from either extremity towards this point of neutrality.

These remarkable effects are solely the result of the action of electricity at a distance; for they take place in an equal degree whatever non-conducting substance may be interposed between the bodies exerting this influence on one another. But in an experiment where the acting body, instead of being an electric, is a conducting body, the electrical state which the globe induces on the cylinder must re-act upon its own electricity.

The negative electricity, that is, the under-saturated matter at the nearer end of the cylinder, must exert a tendency to induce positive electricity in the globe, and more especially upon the side next the cylinder; that is, it will tend, by its attraction for the fluid, to draw it to that side, and thus render it still more highly positive than it was before. This can only be done at the expense of the other side, from which the fluid must be taken, and which is therefore rendered less charged with fluid, that is, less positive, than before. But this new distribution of the electric fluid in the globe, by increasing the positive state of the side next the cylinder, tends to augment its inductive influence on the fluid in the cylinder, that is, to drive an additional quantity of fluid from the negative to the positive end. This must be followed in turn by a corresponding reaction on the globe, and so on, constituting a series of smaller adjustments, until a perfect equilibrium is established in every part. This reasoning is fully established by experiment. All that is required for its illustration is simply to furnish the metallic globe, insulated and charged with positive electricity, with electroscopes upon its opposite surfaces. No sooner do we bring near to it a conducting body than the balls of the electroscope, at the side most distant from that body, begin to collapse, while those at the nearer side diverge to a greater degree than before; thus showing the nature of the reflex operation of the induced electricity of the conductor upon the body from which the induction originated.

In all the changes thus alluded to, there has been no transfer of electricity from either of the bodies to the other, as is most satisfactorily proved by the circumstance that the mere removal of the

ELECTRICITY.

Fig. 8.

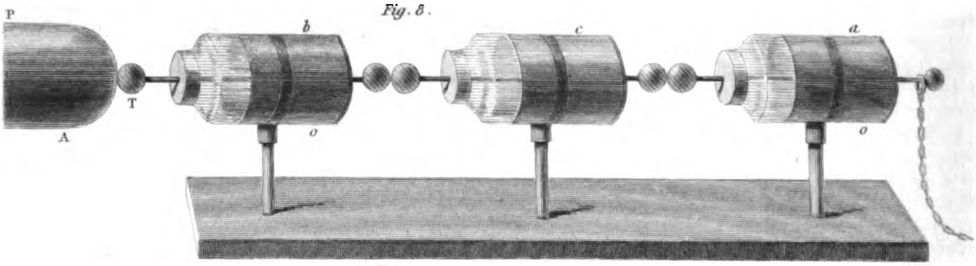

Fig. 9.

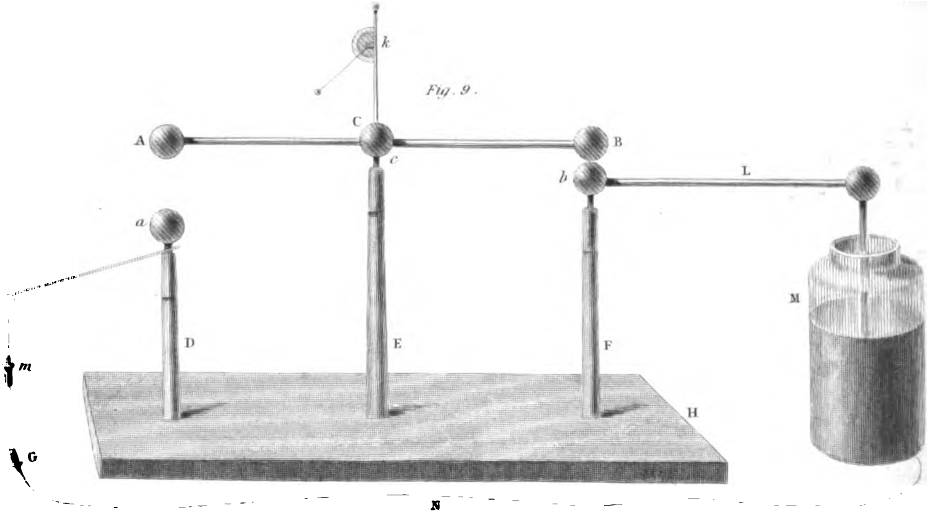


bodies to a distance from one another is sufficient to restore each of them to its original state. The globe remains as perfectly electrified as before; the cylinder returns to its condition of perfect neutrality; and the experiment may be repeated as often as we please, without any variation in the phenomena. This would not be the case, however, if the cylinder were divided in the middle, and one or both of the parts were removed separately, while they still remained under the influence of the globe. The return of the electric fluid from the positive to the negative end being thus prevented, each part will retain, after its separation, the electricity which had been induced upon it; the nearer portion will remain negative, the remoter one positive. If the division had been in three parts, the middle part only would have been neutral.

It is found by experiment that the effects of induction on a conductor are augmented by increasing its length; and they become as great as possible by placing the conductor in communication with the earth, which carries off all the fluid the electrified body is capable of expelling from the nearest end. A conductor under the influence of induction, between which and the earth a communication has been made, by touching the remote end with a metallic rod held in the hand, possesses but one kind of electricity, namely, the one opposite to that of the electrified body which is acting upon it. The part touched is brought into a state in which it appears to be neutral, as long as it remains in the vicinity of the electrified body; but it really contains less fluid than its natural share; and this will immediately become apparent if the conductor that has been touched be again insulated, and then removed from the influence of the body producing the induction.

This peculiar condition of a body, in which its parts are really undercharged or overcharged with fluid, although, from the action of electric forces derived from bodies in its vicinity, a state of equilibrium is established, and no visible effect results, has been denominated by Biot *disguised electricity*. We have hitherto supposed the acting body to be positively electrified; but precisely the same effects would happen with regard to the degree, although opposite as to the species of electricity, if it had been negatively electrified. Our knowledge of the induction of electricity enables us to understand why bodies between which it takes place should attract one another. For the action of the adjacent sides which are brought into opposite electrical states is greater than the action of those sides which are in the same electrical states, and which are more distant; hence the attractive force always exceeds the repulsive.

The most convenient mode of obtaining an accumulation of electricity arising from induction is by the employment of coated glass, that is, of a plate of glass on each side of which is pasted a sheet or coating of tin-foil. Care must be taken to leave a sufficient margin of glass uncovered with the metal for preventing the transfer of electricity from one coating to the other, round the edge of the glass; and all sharp angles or ragged edges in the coatings should be avoided, as they have a great tendency to dissipate the charge.

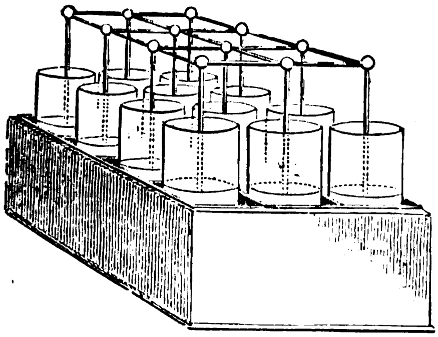
The form of coated glass best adapted to experiments is that of a cylindric jar; this is coated, within and without, nearly to the top. The cover consists of baked wood, and is inserted with sealing wax, to exclude moisture and dust. A metallic rod, rising two or three inches above the jar, and terminated at the top in a brass knob, is made to descend through the cover till it touches the interior coating. The name of the *Leyden phial*, or *jar*, is applied to this instrument. It is used in the following manner: the outer coating being made to communicate with the ground, by holding it in the hand, the knob of the jar is presented to the prime conductor when the machine is in motion; a succession of sparks will pass between them, while, at the same time, nearly an equal quantity of electricity will be passing out from the exterior coating, through the body of the person who holds it, to the ground. The jar, on being removed, is said to be charged; and if a communication is made between the two coatings, by a metallic wire, extending from the external one to the knob, the electric fluid which was accumulated in the positive coating rushes, with a sudden and violent impetus, along the conductor, and passes into the negative coating; thus at once restoring an almost complete equilibrium. This sudden transfer of a large quantity of accumulated electricity is a real explosion; and it gives rise to a vivid flash of light, corresponding in intensity to the magnitude of the charge. The effect of its transmission is much greater than that of the simple charge of the prime conductor of the machine; and it imparts a sensation, when passing through any part of the body, of a peculiar kind, which is called the *electric shock*.

The arrangement of the parts in a Leyden jar, as well as the mode of charging and discharging it, is shown in several figures of *Plate* 2, ELECTRICITY. It may be proper to state, that *talc* or *mica* is as well fitted for electrical purposes as glass; and, owing to the extreme thinness of its *laminæ*, it is more readily put in operation. It is also more durable.

In the construction of the Leyden jar, the thickness of the glass is an important consideration. The thinner the glass the greater will be the power of taking a charge; but the power of retaining it will be less, on account of the diminished resistance which the glass will oppose to the electricity through it. If the charge be higher than what the jar will bear, the glass will be broken by the violence with which the electric fluid forces a passage through its substance. Another limit to the charge which a jar is capable of retaining arises from the liability of the electricity to pass from one coating to the other, round the edges of the glass. The deposition of moisture, also, on the glass, will occasion a spontaneous discharge, since it forms a chain of conducting particles, in the very line which the electricity has a tendency to take. Hence, in order to preserve the uncoated part of the glass in as dry a state as possible, it is usually covered with a layer of sealing-wax, or some other resinous varnish.

By uniting together a sufficient number of jars, we are able to accumulate an enormous quantity of electricity: for this purpose, all the interior coatings of the jars must be made to communicate by metallic rods, and a similar union must be established among the exterior coatings. When thus arranged, the whole series may be charged, as if they formed but one jar; and the whole of the accumulated electricity may be transferred from one system of coatings to the other, by a general and simultaneous discharge.

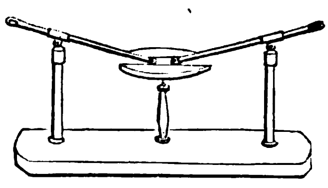
Such a combination of jars is called an *electrical battery*.



An arrangement of this description is represented above, in which twelve jars are united in one box, and the whole series connected together by wires and balls.

For the purpose of making a direct communication between the inner and outer coating of a jar or battery, by which a discharge is effected, an instrument called the *discharging rod* is employed. It consists of two bent metallic rods, terminated at one end by brass balls, and connected at the other by a joint, which is fixed to the end of a glass handle, and which, acting like a pair of compasses, allows of the balls being separated at different distances. When opened to the proper degree, one of the balls is made to touch the exterior coating, and the other ball is then quickly brought into contact with the knob of the jar, and thus a discharge is effected, while the glass handle secures the person holding it from the effects of the shock.

If we wish to send the whole charge of electricity through any particular substance which may be the subject of experiment, we must so arrange the connecting conductors as that the substance shall form a necessary part of the *circuit of the electricity*, as it is termed. With this view, we must place it between two good conductors, one of which is in communication with the outer coating; and the circuit may then be completed by connecting the other conductor with the inner coating, by means of a discharging rod, to one branch of which, if necessary, a flexible chain may be added. A very useful apparatus of this kind is shown beneath.



VII. In forming arrangements for directing the passage of accumulated electricity, it should be borne in mind that the electric fluid will, on these occasions, always pass through the best conductors, although they may be more circuitous, in preference to those which are more direct but have inferior conducting power; and it must also be recollected that, when different paths are open for its transmission along conductors of equal power, the electricity will always take that which is the shortest. Thus, if a person, holding a wire between his hands, discharges a jar by means of it, the whole of the fluid will pass through the wire, without affecting him; but, if a piece of dry wood be substituted for the wire, he will feel a shock; for, the wood being a worse conductor than his own body, the charge will pass through the latter, as being the easier, although the longer circuit. During its transit through the human body, in like manner, the shock is felt only in the parts situated in the direct line of communication; and if the charge be made to pass through a number of persons, who take one another by the hand, and form part of the circuit between the inner and outer coatings of the jar, each will feel the electric shock in the same manner and at the same instant; the sensation reaching from hand to hand, directly across the breast. By varying the points of contact, however, the shock may be made to pass in other directions, and may either be confined to a small part of a limb, or be made to traverse the whole length of the body, from head to foot.

By accurate experiments it appears that the force of the electric shock is weakened, i. e. its effects are diminished, by employing a conductor of great length for making the discharge. But it is difficult to assign a limit to the number of persons through whom even a small charge of electricity may be sent, so that all shall experience the shock, or to the distance along which it may be conveyed by good conductors. The abbé Nollet passed an electrical shock through 180 of the French guards, in the presence of the king; and the sensation was felt at the same moment by all the persons composing the circuit.

An experiment was made near London, at a time when the ground was remarkably dry, to ascertain if any loss of time accompanied the passage of the fluid, when transmitted through considerable distances. It was made to perform a circuit of four miles; being conducted for two miles along wires supported on baked sticks, and for the remaining distance through the dry ground. As far as could be ascertained, by the most careful observation, the time in which the discharge was transmitted along that immense circuit was perfectly instantaneous. It may be proper to state that Mr. Wheatstone has lately invented a very ingenious instrument, which possesses the power of measuring the velocity with which electricity is transmitted.

A retardation in the passage of electricity does take place if the conductor be not of a sufficient size; and when this is the case, as well as in those instances where the conductor is not a good one, the discharge will not be effected so instantaneously or so completely. Under these circumstances, also, there is a tendency in the fluid to diverge from the direct line of its course, and to fly off to different objects in the vicinity, as is often exemplified in the case of lightning, which, on striking a building, is apt to take a very irregular and seemingly capricious route, darting towards conducting bodies which may happen to attract it, although at some distance from the immediate direction it was pursuing. The motion of electricity through perfect conductors is attended with no perceptible alteration in the mechanical properties of the conducting bodies, provided they be of sufficient size for the charge of the electric fluid transmitted. On the contrary, very considerable effects are produced when a powerful charge is sent through a wire which is too small to allow the whole quantity to pass with perfect freedom, or

through an imperfect conductor, though of a large size, as is proved when a tree is struck by lightning. A piece of dry writing paper, as well as pieces of dry, porous wood, are easily torn in pieces by an electric charge.

There is a mode of charging a series of jars, which in small batteries might be practised with advantage. A series of three jars is shown at *Fig.* 8, *Plate* 2. The electricity is supplied by the prime conductor, P, which passes from the end, A, to the inner coating of the jar T. The jars are supported by the rings and stands *a b c*. The external surface of the jar *a*, to become negatively electrical, must discharge a portion of its electricity to the inner coating *q*, of the next jar, and so on through the series. If these be afterwards separated, and the whole of the balls united together, a perfect battery must result.

The simple bent discharging rod, for restoring the electrical equilibrium without the operator receiving the charge of the jar, is shown at *Fig.* 7, *Plate* 2, in which E represents the insulating handle, and A the ring of brass reaching from the ball to the external coating.

VIII. Electricity exerts a most extensive and important influence in effecting changes in the temperature and chemical composition of bodies. The ignition and fusion of metals by the electric charge, are phenomena which have been long observed. Thus, by passing a strong charge through slender iron wires, or the finest flatted steel, called *pendulum wire*, they are ignited, and partly melted into globules, and at the same time partially oxidated. If a slip of gold or silver leaf be placed on white paper, and a strong shock passed through it, the metal will disappear with a bright flash; and the impulse with which its particles are driven against the paper will produce a permanent stain of a purple or gray colour. The colours produced in this way have been applied to impress letters or ornamental devices on silk and on paper. For this purpose, the outline of the required figure should be first traced on thick drawing paper, and afterwards cut out in the manner of stencil plates. The drawing paper is then placed on the silk or paper intended to be marked; a leaf of gold is laid upon it, and a card over that; the whole is then placed in a press or under a weight, and a charge from a battery sent through the gold leaf. The stain is confined, by the interposition of the drawing paper, to the limit of the design, and in this way a profile, a flower, or any other outline figure, may be very neatly impressed.

There is an instrument contrived by the late Mr. Cuthbertson, which is well fitted for exhibiting this and other effects of a similar character. It is represented at *Fig.* 9, *Plate* 2, Electricity, and consists of a base, H, supporting an upright pillar of glass, E. The beam, A B, revolves on an axis, or fulcrum, C, and above all is placed the electrometer, *k*. A Leyden jar is shown at M, provided with a communicating wire, *m*, which unites it with the ball *a*, supported by the glass leg, D. Another glass column, F, is provided with a brass ball, *b*, and rod, L, leading to the interior of the jar. If we now suppose the object of the experimentalist be to strike a figure or flower by electricity, it is only necessary to make it part of the circuit, and when the jar is charged so high that its repulsive power will cause the ball B, to ascend, a wire concealed within keeps up the communication with *b*, and the other extremity of the balance, A, by dropping to *a*, makes the communication complete. Inflammable bodies may also be fired by the tubes shown at *m*.

The heat evolved by electricity, like most other of its effects, is in proportion to the resistances opposed to its passage. A rod of wood, of considerable thickness, being made part of the circuit, has its temperature sensibly raised by a very few discharges. Most combustible bodies are capable of being inflamed by electricity. Thus alcohol, ether, camphor, powdered resin, phosphorus, or gunpowder may be set on fire. And the sparks taken from a piece of ice are as capable of inflaming bodies as those from a piece of red-hot iron. The oxidation of metals, through which accumulated electricity has been passed, is rather to be ascribed to the tendency which they are known to possess of combining with the oxygen of the atmosphere when heated, than to any peculiar agency of electricity. A reverse process, however, is found to attend electrical discharges through metallic oxides, extricating their oxygen, and restoring them to their metallic state.

When a succession of electric discharges from a powerful electric machine are sent through water, a decomposition of that fluid takes place, and it is resolved into its two elements of oxygen and hydrogen, which immediately assume the gaseous form. When this experiment is conducted in a suitable apparatus, and a shock is transmitted through the mixed gases thus obtained, they are instantly kindled; a reunion of the elements takes place; and precisely the same quantity of water is reproduced as was decomposed to furnish the gases.

It may appear somewhat paradoxical that the same agent should, in the course of the same experiment, produce at one time decomposition, and at another combination, of the same elements. The simplest way of reconciling this apparent discordance, is to suppose that the combination of the gases is the effect of the heat evolved during its forcible transit through an aeriform fluid that opposes considerable resistance to its passage; while the decomposition of the liquid is the direct consequence of the agency of electricity in its chemical character, when not interfered with by heat.

When a solution of sulphate of copper is subjected to the action of electricity by means of slender conducting wires terminating in the vessel containing the solution, the copper is revived, or precipitated in a metallic state, around the negative wire; but, upon reversing the direction of the current of electricity, so that the same wire now becomes positively electrified, the copper which has collected around it is redissolved, and a similar deposit takes place on the opposite wire, which now becomes the negative one. Similar experiments, made with other metallic solutions, are attended with similar results; and solutions of neutral salts with alkaline and earthy bases obey the same law, being separated into their constituent parts, the ingredient containing oxygen always appearing at the positive wire, and the base at the negative wire; but as these are a class of effects which have been more particularly investigated by that mode of agency denominated *galvanism*, we shall reserve a more full account of them for that article.

IX. Having seen the effects of electricity on inanimate matter, we now proceed to describe the

agency it exerts over living bodies. Its passage through living plants immediately destroys the vitality of the parts through which it passes. A very small shock, sent through the stem of a balsam, causes its leaves to droop in a few minutes, and finally extinguishes its vitality. The approach of an electrified conductor to the sensitive plant (*mimoso pudica*) produces no effect upon it; but when sparks are taken from it, the leaves collapse, just as they are accustomed to do from concussions of a mechanical nature.

When the energetic effects of the shock from the Leyden jar upon the animal system were first made known, high expectations were raised that electricity would prove a remedial agent of extrordinary power. It was supposed that, as a stimulant, it would have many advantages over other remedies; for it can be administered in various degrees of intensity, which may be regulated with great exactness; and its application can be directed especially to the organ we wish to affect. Accordingly, we find, at one period, it was employed in a great number of cases; but at present it is confined to a very few; such as palsy, contractions of the limbs, rheumatism, St. Vitus's dance, some kinds of deafness, and impaired vision.

A very good electrical machine for medical purposes is represented at *Figs.* 2 *and* 3, *Plate* 1, Electricity. An end view of the machine is given in *Fig.* 2, and a front view at *Fig.* 3. F represents the plate, and A the frame of the machine. The handle is shown at I, and the prime conductor at O. H G, is the jar for communicating shocks to the patient, the amount being regulated by the discharger K. The whole machine is held down to the table by the clamp N, which, resting on the board B C, ensures stability to the whole.

There is another form of the electrical machine which is much used in this country. It consists of a plate of glass, placed vertically, and is represented at *Fig.* 1, *Plate* 1, of Electricity. The apparatus is supported by the mahogany base A A, provided with uprights, C, supporting a cross plate at D. The plate H K is pressed by the cushions, *g g*, which, with the rod M, also support the flaps of silk, *a a*. The prime conductor proceeds from the front of the machine, and is placed horizontally at I. Directly we give motion to the plate, the electricity is excited by the friction of the rubbers, and, being collected by the points in the prime conductor, serves to charge jars and perform a variety of amusing experiments.

Although the effects of ordinary shocks upon living animals are familiar to most persons, still a short account of these shocks, as they have been administered out of the common course may not be uninteresting. If a person who is standing receive a charge through the spine, he loses his power over the muscles to such a degree, that he either drops on his knees, or falls prostrate on the ground. A strong charge passed through the head gives the sensation of a violent but universal blow, and is followed by a transient loss of memory and indistinctness of vision. If the diaphragm be included in the circuit of a coated surface of two feet in extent, fully charged, the sudden contraction of the muscles of respiration will act so violently upon the air in the lungs, as to occasion a loud and involuntary shout; but if the charge be small, a fit of convulsive laughter is induced, producing a most ludicrous scene to the by-stander. Small animals, such as mice and sparrows, are instantly killed by a shock from 30 square inches of glass.

X. There are several mineral bodies, which, from being in a neutral state at ordinary temperatures, acquire electricity simply by being heated or cooled. This property is confined to crystallized minerals; and of these the most remarkable are the tourmaline and boracite. In the former of these, it is best observed in the regularly terminated crystals. When one of these is heated from 100° to 212° Fahr. the extremity terminated by the greatest number of planes becomes charged with positive electricity, while the other extremity is negative. When the crystal is of considerable size, flashes of light may be seen along its surface.

A large number of substances become electrified on passing from the liquid to the solid form. This happens to sulphur, gum-lac, bees-wax, and, in general, all resinous bodies. The conversion of bodies into the state of vapour, as well as the condensation of vapour, is generally attended by some alteration of their electrical condition. Thus, if a red-hot platina crucible be placed upon the gold leaf electrometer, and water be dropped into it, at the moment the vapour rises, the leaves of the electrometer diverge with negative electricity.

Electricity is evolved by the contact of different metals. Thus, if two discs, the one of copper, the other of zinc, rather more than two inches in diameter, and furnished with insulating handles, be brought into contact, and then separated and examined by an electroscope, the copper disc is found to be charged with negative, and the zinc disc with positive electricity. While the contact of the metals is preserved, neither of them gives any indication of its electrical state, the electricity being disguised until the separation takes place. This observation has an important relation to the theory of that mode of electrical excitement called *galvanism*, under which head it will be resumed.

There are some bodies which are rendered electrical by pressure. Thus, if a crystal of calcareous spar or arragonite be pressed for a few moments between the fingers, it exhibits a decided attraction. The same thing happens with regard to cork, paper, and wood. Many mineral substances, when reduced to powder, exhibit electricity, if made to fall upon an insulated metallic plate, a mode of excitation which is to be considered as a species of friction.

The most important circumstance in this inquiry is the connection between electricity and the chemical properties of matter, first pointed out by Sir H. Davy. Most of the substances that act distinctly upon each other electrically, are likewise such as act chemically, when their particles have freedom of motion. This is the case with the different metals, with sulphur and the metals, with acids and the alkaline substances. Of two metals in contact, the one which has the greatest chemical attraction for oxygen acquires positive electricity, and the other the negative.

XI. The resemblance between the electric spark, and more especially the explosive discharge of the Leyden jar, and atmospheric lightning and thunder, struck the mind of Doctor Franklin with so much force, that he was determined, if possible, to verify their identity by experiment.

Having constructed a kite, by stretching a large silk handkerchief over two sticks in the form of a cross, on the appearance of an approaching storm,

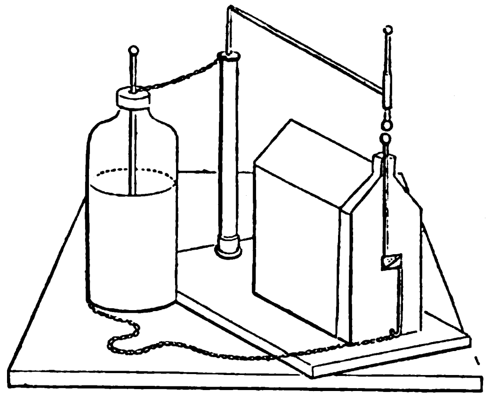
he went into a field in the vicinity of Philadelphia, and raised it, taking care to insulate it by a silken cord attached to a key, with which the hempen string terminated. No sooner had a dense cloud, apparently charged with lightning, passed over the spot on which he stood, than his attention was arrested by the bristling up of some loose fibres on the hempen string: he immediately presented his knuckle to the key, and received an electric spark. The rain now fell in torrents, and, wetting the string, rendered it conducting in its whole length; so that electric sparks were now collected from it in great abundance.

This celebrated experiment was made in June, 1752; and although the same idea which led Franklin to institute it had occurred to other philosophers, yet to him belongs, exclusively, the credit of the discovery. The discovery of Franklin immediately engaged the attention of European philosophers; one of whom, professor Richmann, of St. Petersburg, fell a victim to his attempt to draw down the electric fluid from the clouds. He had constructed an apparatus for observations on atmospherical electricity, and was attending a meeting of the Academy of Sciences, when the sound of distant thunder caught his ear. He immediately hastened home, taking with him his engraver, Sokolow, in order that he might delineate the appearances that should present themselves. While intent upon examining the electrometer, a large globe of fire flashed from the conducting rod, which was insulated, to the head of Richmann, and, passing through his body, instantly deprived him of life. A red spot was found on his forehead, where the electricity had entered; his shoe was burst open, and part of his clothes singed. His companion was struck down, and remained senseless for some time; the door-case of the room was split, and the door itself torn off its hinges.

The atmosphere is very generally in an electrical state. This is ascertained by employing a metallic rod, insulated at its lower end, elevated at some height above the ground, and communicating with an electroscope. In order to collect the electricity of the higher regions of the air, a kite may be raised, in the string of which a slender metallic wire should be interwoven. The atmosphere is almost invariably found to be positively electrified; and its electricity is stronger in the winter than in the summer, and during the day than in the night. From the time of sunrise, it increases for two or three hours, and then decreases towards the middle of the day, being generally the weakest between noon and four o'clock. As the sun declines, its intensity is again augmented, till about the time of sunset, after which it diminishes, and continues feeble during the night.

In cloudy weather, the electrical state of the atmosphere is much more uncertain; and when there are several strata of clouds, moving in different directions, it is subject to great and rapid variations, changing backwards and forwards in the course of a very few minutes. On the first appearance of fog, rain, snow, hail, or sleet, the electricity of the air is generally negative, and often highly so; but it afterwards undergoes frequent transitions to opposite states. On the approach of a thunder-storm, these alternations of the electric condition of the air succeed one another with remarkable rapidity. Strong sparks are sent out in great abundance from the conductor; and it becomes dangerous to prosecute experiments with it in its insulated state. Thunder is merely the noise produced by the motion of the lightning.

The mode of protecting buildings from the effects of lighting will be best shown by a diagram.



It represents a small wooden model of a house, from the top of which a rod descends attached to a chain passing to the external coating of a Leyden jar. A similar chain connects the internal coating with a metal rod supported by a glass pillar. If we now suppose the jar to be charged by the action of a machine, the upper rod will represent a cloud positively electrified, and if no break occurs in the conductor the electrical equilibrium will be restored. In the figure a small interruption occurs in the circuit, and at that point an explosion happens, so that the brick is thrown out. Models of this description are sometimes provided with a receptacle for holding powder or other inflammable matter, which is ignited by the passage of the electric fluid.

The protection of buildings from the destructive effects of lightning is the most important practical application of the theory of electricity. The conductors, for this purpose, should be formed of metallic rods, pointed at the upper extremity, and placed so as to project a few feet above the highest part of the building they are intended to secure; they should be continued without interruption till they descend into the ground below the foundation of the house. Copper is preferable to iron as the material for their construction, being less liable to destruction by rust, or by fusion, and possessing also a greater conducting power. The size of the rods should be from half an inch to an inch in diameter, and the point should be gilt, or made of platina, that it may be more effectually preserved from corrosion.

An important condition in the protecting conductor is, that no interruption should exist in its continuity from top to bottom; and advantage will result from connecting together by strips of metal all the leaden water-pipes, or other considerable masses of metal in or about the building, so as to form one continuous system of conductors, for carrying the electricity by different channels to the ground. The lower end of the conductors should be carried down into the earth, till it reaches either water, or at least a moist stratum.

For the protection of ships, chains, made of a series of iron rods linked together, are most convenient, on account of their flexibility. They should extend from the highest point of the mast some way

into the sea, and the lower part should be removed to some distance from the side of the ship, by a wooden spar or outrigger.

Electrical Condenser. In cases of electrical investigation in which the intensity is very low, the condenser becomes a valuable adjunct to the electrometer. It is shown at *Fig.* 5, *Plate* 2, Electricity, and consists of a disc of brass attached to a delicate electrometer, in the front of which is placed another moveable plate. Volta appears to have been the first electrician who constructed an apparatus of this description. His condenser of electricity consisted of a flat and smooth metal plate, furnished with an insulating handle, and a semi-conducting or imperfectly insulating plane. The principle on which the action of this apparatus depends, is that the metal plate, whilst standing contiguous to the semi-conducting plane, will both absorb and retain a much greater quantity of electricity than it can either absorb or retain when separate, its capacity being increased in the former, and diminished in the latter case.

This condenser has been greatly improved by Mr. Cavallo, who employed a small metallic plate about the size of a shilling, having affixed to it a glass handle covered with sealing-wax. When the latter plate appeared so slightly electrified by the communicated electricity as not to effect the electrometer, he then placed the small plate on the plane, and touched it with the edge of the large one, holding the latter in an almost vertical position; the small plate was thus found to indicate a very sensible degree of electricity.

Electrical Doubler. This instrument bears some analogy to the one we have already described. It is shown in its simplest form at *Fig.* 5, *Plate* 1, Electricity. In the centre is placed a brass ball supported by a glass leg. There are two brass plates or discs, A C, which are stationary, and a moveable one which is made to revolve with a handle. The precise mode of operation can however only be understood by referring to another view of the instrument. A C, *Fig.* 6, represents the same discs as in the former figure, and the moveable plate is shown at B. The insulating handle is indicated at L P. M represents the top of the stand on which the whole apparatus revolves, and G and H two projecting arms. Small wires also project at E F. If we suppose a faint degree of electricity communicated to the disc B, and it is brought opposite A, the stratum of air between operates like a plate of glass, and by induction A becomes negatively charged, and will receive electricity, but on withdrawing B, the plate A will give a powerful spark. This is given between E and G. A similar effect is found to occur between F H, each time the effect being encreased. D forms a species of prime conductor.

Electrometer Gold Leaf. We have already described several instruments for measuring the intensity of electrified bodies, and have fully examined the principle of their construction. But the one contrived by Mr. Singer is so valuable for its simplicity and delicacy of construction as to warrant a particular notice. The instrument is shown at *Figs.* 3 and 4, *Plate* 2, Electricity. The first represents the external form, and the latter, the internal construction. The following brief description will suffice to convey a correct idea of it. It is formed of a glass cylinder surmounted by a broad cap of either wood or metal. The insulation depends on a glass tube of four inches long, and one fourth of an inch in diameter, covered on both sides with sealing-wax, and having a brass wire of a sixteenth of an inch thick and five inches long, passing through its axis, so as to be perfectly free from contact with any part of the tube in the middle of which it is fixed by a plug of silk, which keeps it in a concentric position with the internal diameter of the tube. A brass cap is screwed upon the upper part of this wire; it serves to limit the atmosphere from free contact with the outside of the tube, and at the same time to defend its inside from dust. To the lower part of the wire the gold leaves are fastened. The glass tube passes through the centre of the cap of the electrometer, and is cemented there about the middle of its length. When this construction is considered, it will be evident, that the insulation of the wire, and also of the gold leaves, will be preserved, until the inside as well as the outside of the glass tube becomes coated with moisture; but so effectually does the arrangement preclude this, that some of these electrometers have remained for years, without being either warmed or wiped, and have still appeared to retain the same insulating power as at first.

Electrophorus. This is a very cheap piece of apparatus, and is frequently employed as a substitute for the electrical machine. It is represented at *Fig.* 6, *Plate* 2, Electricity. The construction is exceedingly simple and may be easily understood. Procure two circular plates of metal, or of wood covered with tin-foil, carefully rounded at the edges; these are the conductors; between them is placed a resinous plate, formed by melting together equal parts of shell-lac, resin, and Venice turpentine, and pouring the mixture, whilst in a fluid state, into a hoop formed of tin of the required size, placed on a marble table, from which the plate may be easily separated when cold. This plate should be about half an inch in thickness; it is sometimes made by pouring the mixture on one of the conductors, which is then formed with a rim for that purpose. In the centre of the upper conductor is fixed a glass handle, A, that it may be lifted without drawing off its electricity, and when the electric state of the lower conductor is to be examined, the whole apparatus must be placed on an insulating stand.

To use the electrophorus the upper surface of the resinous plate must be excited with a piece of dry fur, and it will be electrified negatively. Place the upper conductor, *c*, upon it, and then raise the same by its insulating handle; it will be found to exhibit very faint, if any, electrical signs. Replace the conductor, and whilst it lies on the surface of the excited plate, touch it with a finger or any other uninsulated conductor, and then raise it again by its handle. It will now be positively electrified, and afford a spark at B. If it be then placed on the resinous plate, touched and again raised, another spark will be procured, and this process may be repeated for a considerable time without any perceptible diminution of effect.

The facility with which inflammable air is lighted by even a moderate electric spark, suggested to Volta the construction of an inflammable air lamp: it consists of a reservoir filled with hydrogen gas subject to the constant pressure of a column of water, and confined by a stop-cock, which, when opened, permits it to escape in a slender stream from a small aperture. In a box beneath the vessel of gas an electrophorus is placed, and a wire passes through a glass tube from the upper part of this box to the opening of the stop-

cock. The cover of the electrophorus is connected by a silk string with the handle of the stop-cock, so that the same motion that opens the cock raises the cover of the electrophorus, and the spark that passes from it is conveyed by the insulated wire to the stream of gas, which it inflames.

ELECTRO-MAGNETISM; the name applied to a very interesting class of facts, principally developed by Sir Humphry Davy, Professor Faraday, and Professor Oersted, of Copenhagen. The power of lightning in destroying and reversing the polarity of a magnet, and of communicating magnetic influence to iron previously not magnetic, had long been observed, and had led to the supposition that similar effects might be produced by the common electrical or galvanic apparatus. The first observation of Professor Oersted was, that an electrical current, such as is supposed to pass from the positive to the negative pole of a voltaic battery, along a wire which connects them, causes a magnetic needle, placed near it, to deviate from its natural position, and to assume a new one, the direction of which depends upon the mode of conducting the experiment. The metallic wire to be made use of, in this experiment, should be two or three feet in length, in order to allow of its being bent or turned by the hands in various directions, and is called the *conjunctive wire*. When the wire is extended horizontally in the line of the magnetic meridian, with a freely suspended compass needle, whose centre is directly under the wire, the needle instantly deviates from the magnetic meridian, and declines towards the west, under that part of the conjunctive wire which is nearest the negative electric pole, or the copper end of the voltaic apparatus, the amount of declination depending upon the strength of the electricity, and the sensibility of the needle. If we change the direction of the conjunctive wire out of the magnetic meridian towards the east or the west, no change in the above result takes place. except that of its amount. But if the wire be disposed horizontally beneath the needle, the effects take place in an inverse manner; i. e. the pole of the needle, under which is placed the portion of the conjunctive wire, which receives the negative electricity of the battery, declines towards the east.

When the conjunctive wire is stretched alongside of the needle in the same horizontal plane, it occasions no declination, either to the east or west; but it causes it merely to incline in a vertical line, so that the pole adjoining the negative influence of the battery on the wire, dips when the wire is on its west side, and rises when it is on the east. If we stretch the conjunctive wire, either above or beneath the needle, in a plane perpendicular to the magnetic meridian, it remains at rest, unless the wire be very near the pole of the needle; in which case it rises when the entrance takes place by the west part of the wire, and sinks when it takes place by the east part. When we dispose the conjunctive wire in a vertical line opposite the pole of the needle, and make the upper extremity of the wire receive the electricity of the negative end of the battery, the pole of the needle moves towards the east; but if we place the wire opposite a point betwixt the pole and the middle of the needle, it moves to the west. The phenomena are presented in an inverse order, when the upper extremity of the conjunctive wire receives the electricity of the positive side of the apparatus.

The foregoing observations induced professor Oersted to believe that the electric action is not inclosed within the conducting wire, but that it has a pretty extensive sphere of activity around it. He also concluded that this influence acts by revolution; for, without such a supposition, it is impossible to conceive how the same portion of wire, which, placed beneath the magnetic pole, carries the needle towards the east, should, when placed above this pole, carry it towards the west. Such was the nature of the first discovery in electro-magnetism. It was no sooner announced, than the experiments were repeated and varied by philosophers in all parts of the world; and a multitude of new facts were soon brought to light through the labours of Davy, Faraday, Ampère, and Biot.

Two very important facts were ascertained by Ampère and Davy,—that the conjunctive wire becomes itself a magnet and that magnetic properties might be communicated to a steel needle not previously possessing them, by placing it in the electric current. The former of these facts is proved by throwing some iron filings on paper, and bringing them under the wire, when they will immediately adhere to it, forming a tuft round it ten or twelve times the diameter of the wire: on breaking the connection with the battery, however, they immediately fall off, proving that the magnetic effect depends entirely on the passage of the electricity through the wire. The degree of force of this magnetic property thus communicated to the uniting wire was imagined, by Sir H. Davy, to be proportional to the quantity of electricity transmitted through it. Hence the finer the wire, the more powerfully magnetic was it rendered; and hence, also, a battery of very large plates, such as is used for producing intense heat and light, was found to give the strongest magnetism to the wire connecting its poles. Accordingly we find that the calorimoter of Dr. Hare, a galvanic arrangement, in which the plates are nearly two feet square, exhibits the strongest magnetic effects, and this, notwithstanding the powerful heating effects that accompany its action; the heat excited not diminishing or interfering with the magnetism, but apparently increasing it; for a fine platina wire, so intensely ignited as to be near the point of fusion, is observed to attract larger quantities of iron filings than when at a lower temperature.

To communicate magnetic properties to steel needles, which before did not exhibit them, it is necessary merely to place them in contact with, or near to, the conjunctive wire. The position in which they are to be placed, with regard to the wire, is important, as the permanence of their magnetic quality depends upon it. If they are placed parallel with it, they lose their magnetism when the connection with the battery is broken, which shows that their magnetism arose only from their forming part of the electric circuit, like the connecting wire itself. But if they are placed across the wire, they become permanently magnetized and retain their power equally with needles prepared in the ordinary way. The polarity is different, however, according as the needle is placed above or below the wire.

When a needle is placed under the uniting wire, the positive end of the battery being on the right hand of the operator, the end of the needle next to him becomes the north pole, and the other end the south pole. On the contrary, when a needle is held above the wire, the reverse of this takes place; the

end next to the observer becomes the south, and the other the north pole. Even the same opposition is observed when needles are placed in a perpendicular position, on different sides of the wire; in those on one side, all the lower ends are found to be north poles, while, in those on the opposite side of the wire, the upper ends are all north poles, and the lower extremities all south poles.

Direct contact of the steel needles with the conjunctive wire is not necessary, for they become instantly magnetic when brought near it, even though thick plates of glass are interposed. As was remarked with regard to the connecting wire, galvanic batteries, consisting of large plates, are most powerful in communicating the magnetic influence.

When the conjunctive wires of two distinct galvanic arrangements are made to approach each other, we observe magnetic attractions and repulsions.—Two wires of copper, silver, or any other metal, connecting the extremities of two galvanic troughs, being placed parallel to each other, and suspended so as to move freely, immediately attract and repel each other, according as the directions of the currents of electricity flowing through them, are the same or different. When both the negative or both the positive extremities of the troughs are turned to the same quarter, so that the electric current passes along each wire in the same direction, the two wires attract each other; but when the position of one of the troughs is reversed, so that the electric currents in the two wires flow in opposite directions, the wires repel each other.

Upon this experiment is founded the most plausible theory of magnetism, viz., that it arises from the attractions and repulsions of currents of electricity, constantly circulating round every magnet. This is conceived to explain the reason why the magnetic needle places itself at right angles to a wire conducting electricity, namely, that the electric current passing along the wire may coincide with that circulating round the magnet. The magnetic effects produced by galvanic arrangements are obtained also by electricity evolved from the common machine, and still more from this power concentrated in the Leyden jar; the magnetism communicated agreeing in every respect as to the permanence of the polarity, the variations when the needle is placed above or below the wire, &c., with that produced by the voltaic pile.

Magnetism is communicated to needles in a different manner from that of placing them across the conjunctive wire. The wire is formed into a hollow screw, or helix, by rolling it round a solid rod, and the needle to be magnetized, wrapped in a paper, or put into a glass tube, is placed in the centre of it, and the communication with the galvanic battery established. This arrangement (according to the theory of M. Ampère) conveys the electric current by the spiral convolutions, round and round the needle, and communicates to it, or developes in it, the electric circulation constituting magnetism. By this contrivance it is found that a maximum effect is obtained in a shorter time than by any other method. The position of the north and south pole varies according as either end of the helix is connected with the positive or the negative pole, which shows that the electric current flows along the uniting wire from the positive or zinc extremity to the negative or copper end of the pile. The electricity of a common machine produces the same effect.

Having alluded to the principal facts relating to electro-magnetic phenomena, the ingenious theory of M. Ampère, by which they are explained more extensively and with more precision than by any other hitherto advanced, deserves to be stated. It is the more deserving of attention, as having led its author to the discovery of some of the most remarkable facts detailed above; and if future researches shall continue to increase its probability, it will no doubt be regarded as one of the finest instances of correct induction, supported by minute experiment, which the history of any science can exhibit. The first principle of this theory has been already stated;—that two currents of electricity attract when they move parallel to each other and in the same direction, and repel when they move parallel to each other in contrary directions. This fact is directly the reverse of the usually observed phenomena of electricity; for it is well known that bodies in the same state of electricity repel each other, and in opposite states attract. Hence M. Ampère infers, that these results are not produced by electricity in its known and common state of tension, but are dependent on properties belonging to electricity, previously unsuspected, and peculiar to it when in motion, or flowing in currents. Electricity, when accumulated, has the power of causing certain effects, particularly attractions and repulsions, which are familiar to us, and are called *electrical;* but when moving in currents, it exerts new powers, and these constitute magnetism.

Reviewing the various experiments which have been enumerated, we find, that the connecting wires of two batteries attract and repel each other, according to the direction of the electric currents flowing through them; that the magnetic needle is, exactly in the same manner, attracted and repelled by a connecting wire, according to the direction of the current of electricity moving through the wire; that the position of the needle may be varied, in almost any degree, by changing the position of the connecting wire; that whenever the electric circuit is broken, this influence on the needle ceases, and is renewed whenever the communication between the poles of the battery is restored; that the connecting wire, of whatever metal it may consist, becomes a perfect magnet, as long as the current flows along it, so as to attract iron filings and small steel needles, without attracting copper filings, or any other metal but iron; that steel needles may be converted into permanent magnets, by simply placing them across the connecting wire; that the electric currents having this magnetizing power are not, like accumulated electricity, confined by glass, or other non-conductors, but pass through all bodies with facility, as magnetism was before known to do; that the magnetizing power is exerted by electricity, whether procured by a galvanic apparatus, or a common machine; that powerful magnets may be formed, by conducting electric currents round steel wires, as in the helix, and that the position of the north and south poles of these magnets depends upon the direction in which the currents are made to move round them.

These, and a great number of other facts, it is conceived, clearly demonstrate the perfect resemblance, or rather identity, of electricity and magnetism.—Magnetic phenomena are thus, in fact, a series of electrical phenomena; and magnetism may, with propriety, form a branch of electricity, under the head of *Electrical Currents.* Though this intimate

relation or identity be admitted, it is not so obvious how, by it, the properties of the common magnet are explained. Currents of electricity, according to the theory, are essential to the production of magnetic phenomena; but these are not obvious in a common magnet. M. Ampère has suggested their existence, however, and has so arranged them theoretically, as to account for a great proportion of magnetic appearances. A magnet he conceives to be an assemblage of as many electrical currents, moving round it in planes perpendicular to its axis, as there may be imagined lines, which without cutting one another, form closed curves round it. Magnetization, he says, is an operation by which there is given to the particles of steel (which, of the more common metals, appears to be the only one capable of being permanently impressed with this power) an electro-motive energy, which causes a circulation of these currents to be continued round them.

The excitation and continuance of this electro-motive action is rendered less improbable, when we consider the electric power developed in the tourmaline and boracite by heat alone, and when we find, as in the electrical columns of De Luc and Zamboni, that electricity may be generated for years without ceasing or diminishing, by a small and simple apparatus. Such, then, is the constitution of a permanent magnet. It is a mass of iron or steel, round the axis of which electric currents are constantly circulating, and these currents attract all other electric currents flowing in the same direction, and repel all others which are moving in an opposite direction.

From these attractions and repulsions another effect follows, that the currents of one magnet have always a tendency to move any other magnet near it, till the currents in the second shall coincide in direction with those of the first. It is from this cause, as will presently be explained, that the magnetic needle always turns to the meridian, and that the needle in Oersted's experiments settled at right angles to the connecting wire. One important circumstance is always to be kept in view, that the electric currents flow round every magnet in the same direction in reference to its poles. If, for instance, we place a magnet with its north pole pointing to the north, in the usual position of the magnetic needle, the current of electricity flows round it from west to east; or, on the eastern side of the magnet, it is moving downwards, and on the western side upwards; on the upper side, from west to east, and on the lower side, from east to west. This, it is found, is a uniform law.

On these principles the phenomena of magnetism are easily accounted for. Thus, to take one of the most obvious and well known facts, that of two magnets attracting when their opposite poles are approached to one another, as the north of one to the south pole of the other. Let us suppose a magnet in the position which has just been stated, with its north pole directed to the north; and let a second magnet be placed beyond it, and in a line with it, with its north pole also pointed to the north. Then, it is obvious that the south pole of the second magnet will be next to the north pole of the first; and from their position it follows, that the electric currents must be flowing in the same direction, or, in both of them, from west to east: hence, as currents moving in the same direction attract, these opposite poles, if within a certain distance, ought to attract each other, which, accordingly, will be found to be the case. Now, let the second magnet be reversed; let its south pole be directed to the north, and its north pole approached to the north pole of the first magnet; the electric currents will flow round the magnet in the same manner as before; but in reference to the first magnet and to the meridian, their direction will be reversed: their direction will now be from east to west, upwards on the eastern side, and downwards on the western; consequently, the currents in the two magnets being now opposite, will repel, or the two north poles will repel each other.

In the experiments of Professor Oersted, it was found, as has been stated, that when the extraneous influence of the magnetism of the earth was counterbalanced, the tendency of a magnetic needle always was to place itself at right angles to the wire connecting the poles of the galvanic battery. The reason of this is easily explained upon the present hypothesis. In the needle, the currents flow round its axis from end to end; but in the connecting wire there is no circulation round the axis, but a constant stream from one end, namely, the negative, to the other, the positive extremity: hence, for the current along the wire to coincide with the current across and round the magnet, it is necessary that the latter shall stand across the former; and as it appears, that from the attractions and repulsions which these electric currents exert, they are able to move one or both of the magnetic bodies (according as they are light and mobile), till they coincide, the needle moves if the wire is fixed till it stands at right angles to the wire; and if the magnet is fixed, and the wire moveable, the reverse happens. The other phenomena, of the needle turning to the west when placed below the wire, to the east when placed above it, &c., may with facility be explained in the same manner by the principles, that currents flowing in the same direction attract; and that in every magnet they move in a constant current, which is, when the north pole is turned to the north, from west to east, or upwards on the west side, and downwards on the east side.

The developement of permanent magnetism in steel needles when placed across the wire, while it is only temporary when they are fastened parallel with it, depends on the same cause: in the latter case, it arises merely from the transmission of electricity from end to end, while, in the former, the electro-motive energy of the particles is developed and called into action, which, when set in motion, seems to have the power of continuing itself. These electric currents have the power, which accumulated electricity has not, of penetrating all substances, as was before known respecting magnetism. This is probably owing to their low state of tension; and, in conformity with this, large plates, which evolve electricity in but a slight intensity, produce magnetic effects most distinctly. The agency of galvanism, and that of common electricity, are equally capable of giving rise to magnetism when flowing in currents, which adds another to the proof that these are the same power.

To complete the view of Ampère's doctrine, it remains only to explain the influence of the earth on the magnet, by which the needle is kept always in one position, nearly coinciding with the meridian. He asserts, that currents of electricity, analagous to those which circulate round every magnet, are con-

stantly flowing round the globe, as the current of electricity in a galvanic apparatus moves in an unbroken circuit from the negative to the positive pole, and from it, by the connecting wire, round again to the negative pole. The direction of these currents he infers to be the same as has been stated with artificial magnets; and it is simply by thé attractions and repulsions of these terrestrial currents, bringing the currents round the needle to coincide with them, that the latter always points to the north.

To detect these currents, and to exhibit their influence without the aid of any common magnet, M. Ampère contrived a small electric apparatus, which was distinctly affected by the magnetic influence of the globe. It consisted merely of a copper wire bent into a circle, with the two extremities brought near to each other. It was supported so as to move with the greatest facility; and the points were immersed in basons of mercury, with which the wires of a galvanic battery were connected.

When the communication was established so as to cause a current of electricity to pass through the circle, it immediately began to move, and, after some oscillations, placed itself nearly at right angles to the meridian, or east and west, or so that the electric current passed downwards on the eastern side, and upwards on the western side. This, it has been stated, is exactly the direction in which the currents in every magnet move (supposing it placed with its north pole to the north). The circle may, therefore, be regarded as a section across the axis of a magnet, or as representing one of the currents flowing round it; and if a number of these circles were placed one beyond another, the farthest would point, like the end of the needle, to the north pole, and the nearest to the south pole. However the experiment was varied, the circle always placed itself east and west: if the galvanic current was, by reversing the connecting wires, made to flow in an opposite direction, the circle turned round a semicircle, and still stood east and west, and so that the electric current should always flow downwards on the eastern side, and upwards on the western side Here, then, are distinct marks of magnetism, particularly that most characteristic one of the axes pointing always to the north, which can be attributed only to the combined influence of electric currents moving round the earth.

The annals of philosophy contain many highly interesting papers on the subject of electro-magnetism; but the only work published in this country which fully combines the experimental with the theoretical branch of the subject is from the pen of Mr. Watkins, Curator of Philosophical Apparatus to the University of London. From this work we may select a few of the most striking experiments.

We have already alluded to the revolution which may be produced in an electrified wire. *Fig.* 1, *Plate* 1, Electro-Magnetism, represents an apparatus for illustrating this phenomenon. It consists of a glass cylinder, mounted upon an iron wire, affixed to a wooden support, and having a copper wire loop passed through the centre of its top, and a metal cup to contain mercury above the wire loop. The soft iron wire of the support projects above the bottom of the glass cylinder, and is rounded at its top. Mercury is placed within the lower part of the glass cylinder, and also in another cup, formed in the wooden support. A platinum wire, having a loop formed at its upper end, is loosely hung to the loop above, and touches the surface of the mercury within the glass cylinder. Upon making a communication with a voltaic battery, by means of two connecting wires placed in the mercury in the upper and lower cups, and bringing a magnet into contact with the lower part of the iron wire, which projects below the wooden support for that purpose, the effects of the electro-magnetic action will be observed by the revolutions of the platinum wire round the iron wire, which is a magnet, whilst the real magnet is kept in contact with it. The wire generates the surface of a cone, its lower extremity the circumference of its base; hence the point of suspension is the vertex, and the iron wire magnet is in the centre of the base.

Fig. 2, represents an apparatus to show the vibratory motion communicated to an electrified wire, from the effects of a magnet. It consists of a wooden basis, upon which is affixed a bent brass standard, having at its upper end a vertical wire screwed into it, which wire supports a cup to contain mercury, and has at its lower end soldered a piece of platinum wire formed into a loop. To this loop is freely hung a light platinum wire, the lower end of which touches the surface of some mercury, which is contained in a trough formed in the wooden basis. Another cup to contain mercury is also affixed to another wire, which passes through the basis into the mercury in the trough. On making a communication with a voltaic battery by means of two connecting wires, as usual, the current is made to pass along the loose platinum wire, and the circuit is thus completed; but no motion of the platinum wire is here perceptible, until a powerful horseshoe magnet is placed in a horizontal position on the basis, with its poles inclosing the pendent wire, when that wire instantly acquires a vibratory motion. On reversing the situations of the connecting wires, or of the poles of the magnet, the vibrations will be in an opposite direction.

Fig. 3, exhibits an apparatus which, when adapted to a fixed stand, illustrates the directive property of the freely suspended electrified wire. It consists of a slender copper wire, bent into a flat spiral coil, its upper end terminating in a reversed hook finely pointed, and its lower end pendent in a line coinciding with the pointed part of the reversed hook. The wire coil is secured to a circular disc of card, the wire from the central coil passing through the card and descending below it. When the straight wire is removed from the apparatus and the flat spiral coil arranged with the point of the reversed hook inserted in the top cup, and its lower extremity dipping into the mercury contained in the trough, the two ends being previously amalgamated, and the coil having free motion about its vertical axis; upon transmitting electricity from a voltaic battery through the spiral coil of copper wire, it has a tendency to range itself in a plane perpendicular to the magnetic meridian, and is also very obedient to the magnet.

Fig. 4, is a view of an apparatus to show the contrary rotation of two electrified wires, each about its respective axis, by the joint effects of electricity and magnetism. It consists of a horseshoe magnet, firmly screwed to a wooden basis or support, two helical coils of copper wire, having slender bars across their tops, with needle points in their centres,

turning in conical holes drilled in the ends of the magnet, and above the points two small platinum cups, to hold a globule of mercury in each. Two wooden cisterns are attached by screws on the lower parts of the magnet, having bent arms fixed in them. To the lower ends of the helical coils are soldered slender pointed wires, bent so as to enter slightly into mercury placed in the two larger cups, mercury being also placed in the small cups. A brass standard affixed to the basis of the apparatus has a forked piece attached to it, with two points descending into the two platinum cups upon the tops of the coils; and there is also another cup placed upon the forked piece to contain mercury. The voltaic circuit is completed by placing wires in the mercury contained in the small side cups, and connected with the copper parts of the batteries; and other wires communicating with the zinc parts are placed in the cup on the top of the apparatus. When the electric stream flows through the apparatus, the helical coils revolve rapidly in contrary directions; but on changing the disposition of the connecting wires, the revolutions of the wires will be reversed. The points of the various wires must be very clean or amalgamated, and the mercury in the cisterns and cups free from dirt.

Fig. 5, represents an apparatus constructed to exhibit the rotation of electrified wires about the poles of a horseshoe magnet, independent of a separate voltaic battery. It consists of a horseshoe magnet, firmly affixed to a metal foot at its bent part; its two ends being made rounding, and having a small hole in the centre of each, at the bottom of which hole an agate cup is placed, and in which, pointed wires affixed to the parts hereafter to be described are made to revolve. A double cylindrical copper vessel, having a bent metal wire affixed to the top of its innermost cylinder, with a vertical wire pointed at both ends, affixed in the middle of that bent wire, is hung upon the upper end of each pole of the magnet, the lower points of the vertical wires of each vessel entering the holes formed, as above described, in the magnet for that purpose. Two hollow cylinders of zinc, each furnished with similar bent wires, having holes made in the underside of each, are then placed within the double copper vessels; the holes in the bent wires being hung upon the uppermost pointed ends of the vertical wires before mentioned. Diluted acid being then poured into the space between the two copper cylinders, the voltaic action commences, and presents the phenomena of the whole of the four cylinders revolving upon their axes; the copper vessels revolving in opposite and contrary directions, and the zinc cylinder turning in opposite directions to them; the rapidity of their revolutions depending upon the strength of the diluted acid, and the delicacy of their suspension. It is evident that a single pair of cylinders may be hung upon one end of a straight or bar magnet placed vertically, and will perform in a similar manner; their rotation being reversed on changing the poles of the magnet. Or a single pair of cylinders may be hung upon either end of a horseshoe magnet if preferred.

Fig. 6, represents an apparatus to exhibit the rotation of two compound rectangular metallic frames about the poles of the magnet, by the mutual influence of a thermo-electric current of magnetism. It consists of a horseshoe magnet supported in a vertical position, upon a brass foot; through a hole made in the curved part of which, a wire passes from the foot, and supports a spirit lamp. In the centre of each upper end of the magnet an agate cup is cemented, in which turns a vertically pointed wire, to the upper end of which two crossing rectangles, or light compound wire frames, are united, composed either of silver and platinum, or platinum and copper; and are united below to wire circles, which surround the arms of the magnet. When the lamp is lighted, the flame heats the lower corners of the rectangles next to it, or rather within it: a thermo-electric current is thereby established in these rectangles, and by its action causes them to rotate in opposite and contrary directions.

There is one more experimental arrangement of the magnetic with the galvanic apparatus, which so fully illustrates the identity of magnetism with galvanism and light as to warrant peculiar attention. This apparatus is now (April, 1833) exhibiting in the National Gallery of Science. The magnet is of the horseshoe form, and is composed of twelve shear steel plates, each twenty-eight inches in length from the poles to the centre edge, three inches wide, and forming together a thickness of four inches. The "keeper" or "bar" is made of the purest soft iron. Around the middle of the "keeper," and occupying with its lower section the space between the poles, is a wooden "winder," having about one hundred yards of common threaded bonnet-wire, from which the two ends, composed of four lengths of the wire twisted together, are carried out, with a vertical curve of about three-fourths of a circle; one of these twisted ends passes beyond each end of the "keeper," and rests upon the respective poles of the magnet. A small wooden lever is so fixed in a frame, to the "winder" and "keeper," as to admit of their being suddenly forced up from the magnet by a sharp stroke; and a very beautiful and brilliant spark is invariably elicited at whichever end of the wire the separation takes place. This spark is capable of igniting gunpowder.

With regard to the cause of the electric currents inferred to be constantly circulating round the globe, it is as yet in obscurity. They are supposed to move at right angles to the magnetic meridian, or nearly parallel with the equator, on the eastern side of the earth moving from us, and on the western side flowing towards us. These currents may be compared to that which flows from the negative pole of a voltaic battery in action, to the positive pole, and, by the medium of the uniting wire, round again to the negative pole. It is conjectured, that the arrangement of the materials of the globe may be such as to constitute a battery, existing like a girdle round the earth, which, though composed of comparatively weak elements, may be sufficiently extensive to produce the effects of terrestrial magnetism. Its irregularity, and the changes which it may accidentally or periodically suffer, may explain the phenomenon of the variation of the compass; or the general action producing the currents of electricity may be affected by different causes, as the earth's motions, currents of the atmosphere, evaporation, or the solar heat. It is supposed that much of the variation depends on the progress of oxidation in the continental regions of the globe. What is called the diurnal variation may be conceived to be produced by the diurnal change of temperature in the superficial layers of the earth, which possess electro-motive energy.

ELECTUARY. Electuaries are medicines chiefly composed of powders of various kinds, mixed up with syrup or honey into such a consistence, that the powders may not separate by keeping. The ingredients of electuaries are chiefly the milder drugs, those which may be taken a good deal *ad libitum*, such as the milder aperients, or aromatics and alteratives, in which a certain latitude may be allowed in the quantity without material risk.

ELEMENT; a term applied in chemistry to a body which has not yet been decomposed. The elements of the ancients were bodies which they supposed to be absolutely simple, and capable of forming all other bodies by their mutual combination; whereas the elements of the moderns are regarded as simple, merely in respect to the present state of the art of analyzing bodies. The progress of chemical science, for several centuries past, has mainly consisted in carrying still farther the analysis of bodies, and in proving those to be compound, which had before been thought elementary.

ELEMI, in *commerce;* a resin obtained from the *Amyris elemifera*, a tree growing in various districts of America, Turkey, &c. It is obtained by wounding the bark in dry weather, the juice being left to thicken in the sun. Its colour is a pale yellow, semitransparent; at first softish, but it hardens by keeping. Its taste is slightly bitter and pungent. Its smell, which is, at first, strong and fragrant, gradually diminishes. It formerly arrived in this country in long roundish cakes, wrapped in flag leaves, but it is now usually imported in mats and chests.

ELEPHANTIASIS; a disease so called from the legs of people affected with it growing scaly, rough, and large, at an advanced period, like the legs of an elephant. The disease attacks the whole body, but mostly affects the feet, which appear somewhat like those of the elephant. It is known by the skin being thick, rough, wrinkled, unctious, and void of hair, and mostly without the sense of feeling. It is said to be contagious. Cullen makes it a genus of disease in the class *cachexiæ*, and order *impetigines*. Elephantiasis has generally been supposed to arise in consequence of some slight attack of fever, on the cessation of which the morbid matter falls on the leg, and occasions a distension and tumefaction of the limb, which is afterwards overspread with uneven lumps, and deep fissures. By some authors it has been considered as a species of leprosy; but it often subsists for many years without being accompanied with any of the symptoms which characterize that disease. It sometimes comes on gradually, without much previous indisposition; but more generally, the person is seized with a coldness and shivering, pains in the head, back and loins, and some degree of nausea. A slight fever then ensues, and a severe pain is felt in one of the inguinal glands, which, after a short time, becomes hard, swelled, and inflamed. No suppuration, however, ensues; but a red streak may be observed running down the thigh from the swelled gland to the leg. As the inflammation increases in all the parts, the fever gradually abates, and, perhaps, after two or three days' continuance, goes off. It, however, returns again at uncertain periods, leaving the leg greatly swelled with varicose, turgid veins, the skin rough and rugged, and a thickened *membrana cellulosa*. Scales appear also on the surface, which do not fall off, but are enlarged by the increasing thickness of the membranes; uneven lumps, with deep fissures, are formed, and the leg and foot become at last of an enormous size.

A person may labour under this disease many years without finding much alteration in his general health, except during the continuance of the attacks; and perhaps the chief inconvenience he will experience is the enormous bulky leg which he drags about with him. The incumbrance has, indeed, induced many who have laboured under this disease to submit to an amputation; but the operation seldom proves a radical cure, as the other leg frequently becomes affected. Hilary observes, that he never saw both legs swelled at the same time. Instances where they have alike acquired a frightful and prodigious size, have, however, frequently fallen under the observation of other physicians.

ELIXIR, is the name of several medicines, consisting of wine or spirits of wine and various resinous, bitter, vegetable substances. The word, however, is almost gone out of use, and its place supplied by *tincture*. Elixirs, indeed, differ from tinctures, by having a thicker and more opaque consistence, and by containing less spirit. The stomach elixirs of Frederic Hoffmann and Stoughton are well known. The former (*elix. viscerale, Fr. Hoffmanni*) is prepared by dissolving in Malaga or Hungary wine the extract of card. ben., cent. min., cort. aurant., cort. Chinæ., myrrh. aq., and adding to the solution a little tinct. caryophyll. aromat. and tinct. croci. Stoughton's elixir consists of absynth., gentian. rubr., rhubarb, cascarilla and cort. aurant., steeped in spirits of wine.

ELL; a measure which is found under different denominations, in most countries, whereby cloths, stuffs, linens, silks, &c., are usually measured. The ell English is 5 quarters, or 45 inches; the ell Flemish, 3 quarters, or 27 inches. In Scotland, an ell contains 37 2-10 inches English.

ELLIPSIS, in *mathematics;* one of the conic sections. Kepler discovered that the planets describe such a curve in revolving about the sun. It presents to the eye, at once, variety and regularity, and is, therefore, preferred by painters to the circle for the outline of their pictures. Two points in the longest diameter have this peculiarity: the sum of two straight lines drawn from them to any point in the circumference is always the same, to whatever point they are drawn. An ellipsis may, therefore, be formed by taking two points upon a plane, attaching to them a ring of thread, and following it round with a pencil, keeping it extended in the form of a triangle. The points where the thread is fixed are called the *foci*.

ELONGATION, in *astronomy;* the angle under which we see a planet from the sun, when reduced to the ecliptic; or it is the angle formed by two lines drawn from the earth to the sun and planet, when reduced as above.

EMANATION; a series of philosophical systems which, like most of the ancient, do not adopt a spontaneous creation of the universe by a Supreme Being. This doctrine came from the East. Traces of it are found in the Indian mythology, and in the old Persian or Bactro-Median doctrine of Zoroaster. It had a powerful influence on the ancient Greek philosophy, as may be seen in Pythagoras.

EMASCULATE; to deprive of virility. This is an operation rarely employed on the human race in our quarter of the globe, though most animals kept for

domestic purposes are made to submit to it. An entire change in the habits and tone of voice is the certain result. Emasculated persons fetch a very high price in the east.

Embalming; to embalm, to fill and surround with aromatic and desiccative substances any bodies, particularly corpses, in order to preserve them from corruption. The ancient Egyptians were the inventors of this art. Other people, for example, the Assyrians, Scythians, and Persians, followed them, but by no means equalled them in it. The art has degenerated very much from the high degree of perfection at which it stood among the ancients; perhaps because the change in religious opinions and customs has made the embalming of the dead less frequent. In modern times, only distinguished individuals are occasionally embalmed; but this process does not prevent corruption.

The intestines are taken out of the body, and the brains out of the head, and the cavities filled up with a mixture of balsamic herbs, myrrh and others of the same kind; the large blood-vessels and other vessels are injected with balsams dissolved in spirits of wine; the body is rubbed hard with spirits of the same kind, &c. (See Mummies.) The ancient Egyptians removed the viscera from the large cavities, and replaced them with aromatic, saline, and bituminous substances, and also enveloped the outside of the body in cloths impregnated with similar materials. These were useful in preventing decomposition, and excluding insects, until perfect dryness took place. In later times, bodies have been preserved a long time by embalming, especially when they have remained at a low and uniform temperature, and have been protected from the air. The body of Edward I. was buried in Westminster Abbey in 1307, and in 1770 was found entire. Canute died in 1036; his body was found very fresh in 1776, in Winchester Cathedral. The bodies of William the Conqueror and of Matilda his wife were found entire at Caen, in the sixteenth century. Similar cases are not unfrequent. In many instances, bodies not embalmed have been preserved from decay merely by the exclusion of the air and the lowness of the temperature. Impregnation of the animal body with corrosive sublimate appears to be the most effectual means of preserving it, except immersion in spirits. The impregnation is performed by the injection of a strong solution, consisting of about four ounces of bichloride of mercury to a pint of alcohol, into the blood-vessels, and, after the viscera are removed, the body is immersed for three months in the same solution, after which it dries easily, and is almost imperishable. *Wet preparations*, or those immersed in alcohol or oil of turpentine, last for an indefinite time. A strong solution of muriate of ammonia is now much employed.

Embargo, in *commerce;* an arrest on ships or merchandise, by public authority; or a prohibition of state, commonly on foreign ships in time of war, to prevent their going out of port, sometimes to prevent their coming in, and sometimes both for a limited time.

Embayed; the situation of a ship when she is enclosed between two capes or promontories. It is particularly applied when the wind, by blowing strongly into any bay or gulf, makes it extremely difficult, and perhaps impracticable, for the vessel thus enclosed to draw off from the shore, so as to weather the capes and gain the offing.

Embossing, or Imbossing, in *architecture* and *sculpture;* the forming or fashioning works in relievo, whether cut with a chisel or otherwise. Embossed glass, made by the action of fluoric acid, is used for a variety of purposes.

Embryo; the first rudiments of the animal in the womb, before the several members are distinctly formed, after which it is called the *fœtus*. The time necessary to produce this is different in different species. The human embryo is visible in three weeks: at the end of four, a pulsation is perceptible, which is known to be the beating of the heart. It is now about the size of an ant or fly, and retains its transparency, which, however, gradually diminishes, and, at the end of two months, disappears: the eyes, nose, mouth, ears, and all the members, are distinguishable: it is as large as a bee. In three months, every thing becomes more distinct, the sex becomes evident, and the fœtus grows until it is ushered into the world as a child.

Emery is chiefly found in shapeless masses, and mixed with other minerals. It contains about 80 parts in 100 of alumine, and a small portion of iron, is usually opaque, and about four times as heavy as water. The best emery is brought from the Levant, and chiefly from Naxos, and other islands of the Grecian archipelago. It is also found in some parts of Spain, and is obtained from a few of the iron mines in Great Britain. In hardness, it is nearly equal to adamantine spar, and this property has rendered it an object of great request in various arts. It is employed by lapidaries in the cutting and polishing of precious stones; by opticians, in smoothing the surface of the finer kinds of glass, preparatory to their being polished; by cutlers and other manufacturers of iron and steel instruments; by masons in polishing of marble; and, in their respective businesses, by locksmiths, glaziers, and numerous other artisans. For all these purposes, it is pulverized in large iron mortars, or in steel mills; and the powder, which is rough and sharp, is carefully washed, and sorted into five or six different degrees of fineness, according to the description of work in which it is to be employed.

Emetic; any medicine which is capable of exciting vomiting, independently of any effect arising from the mere quantity of matter introduced into the stomach, or of any nauseous taste or flavour. The susceptibility of vomiting is very different in different individuals, and is often considerably varied by disease. Emetics are employed in many diseases. When any morbid affection depends upon, or is connected with, over distention of the stomach, or the presence of acrid, indigestible matters, vomiting gives speedy relief. Hence its utility in impaired appetite, acidity in the stomach, in intoxication, and where poisons have been swallowed. In the different varieties of febrile affections, much advantage is derived from exciting vomiting, especially in the very commencement of the disease.

In high inflammatory fever it is considered as dangerous, and in the advanced stage of typhus it is prejudicial. Emetics, given in such doses as only to excite nausea, have been found useful in restraining hæmorrhage. Different species of dropsy have been cured by vomiting, from its having excited absorption. To the same effect, perhaps, is owing the dispersion of various swellings, which has occasionally resulted from this operation. The operation of vomiting is dangerous or hurtful in the following cases: where

there is a determination of the blood to the head, especially in plethoric habits; in visceral inflammation; in the advanced state of pregnancy; in hernia and prolapsus uteri; and wherever there exists extreme general debility. The frequent use of emetics weakens the tone of the stomach. An emetic should always be administered in the fluid form. Its operation may be promoted by drinking any tepid diluent or bitter infusion.

Emetin. This principle was discovered by Majendie and Pelletier, as existing in the root of ipecacuanha, and being apparently the matter in which its emetic power resides. This principle they procured by digesting the ipecacuanha in sulphuric ether, which removes the oily and odorous matter, and afterwards digesting the ipecacuanha in alcohol. This tincture is then evaporated to dryness, a portion of solid matter is obtained, and water is digested on this; it affords by evaporation emetin nearly pure. It may be farther purified by adding acetate of lead, which throws down the emetin combined with oxide of lead. By passing sulphuretted hydrogen through this solution, the oxide of lead is precipitated, and the emetin remains in solution.

Emetin is inodorous, with a bitter and somewhat acrid taste. At the heat of boiling water it remains unchanged; at a higher temperature it swells and decomposes without melting. It appears to be a ternary compound of carbon, hydrogen, and oxygen; it is scarcely affected by exposure to the air, except a slight deliquescence in humid air. It is very soluble in water and alcohol, but not in sulphuric ether. Sulphuric acid decomposes and clears it. Nitric acid dissolves it, forming a red-coloured solution, which, after a disengagement of nitric oxide gas, yields crystals of oxalic acid. Muriatic, acetic, and phosphoric acids dissolve it; from these solutions an alkali precipitates it unchanged. The vegetable and animal principles exert scarcely any action on it.

Emetin is powerfully emetic, one grain being sufficient to occasion a violent vomiting. Its chemical properties are not very distinctive.

Empiric, in *medical history*; an appellation assumed by a sect of physicians, who contended, that all hypothetical reasoning respecting the operations of the animal economy was useless, and that observation and experience alone were the foundation of the art of medicine. *Empiric*, in modern medicine, is applied to a person who sells or administers a particular drug, or compound, as a remedy for a given disorder, without any consideration of its different stages, or degrees of violence, in different constitutions, climates or seasons.

Emulsions; a term applied to the imperfect solutions of the fixed vegetable oils in water. They are obtained by rubbing the seeds affording these oils with water to which a little sugar has been added.

Enamelling; the art of variegating with colours laid upon or into another body; also, a mode of painting, with vitified colours, on gold, silver, copper, &c., and of melting these at the fire, or of making curious works in them at a lamp. This art is of so great antiquity, as to render it difficult or impossible to trace it to its origin. It was evidently practised by the Egyptians, from the remains that have been observed on the ornamented envelopes of mummies. From Egypt it passed into Greece, and afterwards into Rome and its provinces, whence it was probably introduced into Great Britain, as various Roman antiquities have been dug up in different parts of the island, particularly in the Barrows, in which enamels have formed portions of the ornaments. The gold cup given by King John to the coporation of Lynn, in Norfolk, proves that the art was known among the Normans, as the sides of the cup are embellished with various figures, whose garments are partly composed of coloured enamels. Enamels are vitrifiable substances, and are usually arranged into three classes; namely, the transparent, the semitransparent, and opaque. The basis of all kinds of enamel is a perfectly transparent and fusible glass, which is rendered either semitransparent or opaque, by the admixture of metallic oxides. The art of colouring glass seems to be of nearly the same antiquity as the invention of making it; which is proved, not only from written documents, but likewise by the variously coloured glass corals, with which several of the Egyptian mummies are decorated.

White enamels are composed by melting the oxide of tin with glass, and adding a small quantity of manganese, to increase the brilliancy of the colour. The addition of the oxide of lead, or antimony, produces a yellow enamel; but a more beautiful yellow may be obtained from the oxide of silver. Reds are formed by an intermixture of the oxides of gold and iron, that composed of the former being the most beautiful and permanent. Greens, violets, and blues are formed from the oxides of copper, cobalt, and iron; and these, when intermixed in different proportions, afford a great variety of intermediate colours. Sometimes the oxides are mixed before they are united to the vitreous basis. All the colours may be produced by the metallic oxides.

The principal quality of good enamel, and that which renders it fit for being applied on baked earthenware, or on metals, is the facility with which it acquires lustre by a moderate heat, or cherry-red heat, more or less, according to the nature of the enamel, without entering into complete fusion. Enamels applied to earthenware and metals possess this quality. Enamels are executed upon the surface of copper and other metals, by a method similar to painting. Enameling on plates of metal, and painting with vitrified colours on glass, are practised with great success in England.

One of the most curious and useful branches of this art consists in the manufacture of watch dials. The accompanying account gives the process employed at the present time in the best manufactories in Paris.

"The dial plates of clocks and watches are made in a variety of ways. In general they are composed of enamell upon a single plate of copper, unless they are more than a foot in diameter: larger ones are made in separate pieces, which are afterwards joined together; or they are made of glass, placed upon a white ground. Some dial plates are made of silver, gold, and silvered or gilt brass.

"The enamelled dial plates are formed of a thin plate of copper, enamelled upon both sides, and having hours and minutes painted upon the ground. To make one of these dial plates, a thin plate of copper, of the requisite size, is taken, and hammered upon a slightly concave anvil of hard wood, with a convex-headed hammer, which speedily reduces it to the proper convexity: a hole is then made in the middle, which is enlarged with a tool put into it from the

concave side, in order to form a ridge round the hole on the convex side, to retain the enamel when in a melted state. The copper plate is then placed upon the platine of the works, fitted to it by passing a tool through the centre holes of each, and being kept in its place by a vice, the holes for the screws by which the dial-plate is to be fastened to the rest of the works, and that by which the key is to be introduced, are made; which last is to have a ridge round it, for the same purpose as that round the central hole. Copper wires are then forced into the holes by which it is to be attached to the works, and cut to the proper length, after which they are soldered. The plate is cut of such a size, that the edge may be hammered up to form a similar ridge round the whole face.

"The copper plate being thus manufactured, it is cleansed, by being left a short time in water sharpened with a little aqua-fortis, until the surface is perfectly clean; it is then dipped in common water, and brushed with a brush of brass wires.

"The enamel used ought to be very white: it is imported and sold by the ironmongers in flat cakes. The cakes are broken in a hardened steel mortar, and reduced, for the most part, into small pieces, about the size of small grains of sand, as nearly equal as possible. These are first washed in very clear water, and the milky liquor poured off, and left to settle, by which the finer powder is separated. The grains of enamel are then washed again several times with a clear water, and the settlings of the water that is poured off, kept as before, for enamelling the under surfaces of the plate.

"The grains of enamel being thus well washed, they are put into a glass vessel, and aqua-fortis is poured on them, so as to float them about a quarter of an inch. The whole is stirred with a glass or spatula, and the acid left on the enamel for twelve hours, in order to dissolve away the metallic particles it has rubbed off the steel mortar, and which would foul the whiteness of the enamel when applied on the face of the plate. The nitric acid is then poured off; and the enamel washed again with water, until all the acid is got rid of; after which it is again covered with clean water, and kept under it to preserve its cleanness and whiteness.

"Not only the convex face of the dial-plate, or that on which the hours and minutes are to be painted, is enamelled, but also the concave face. This counter-enamelling, as it is called, is necessary, lest, when the enamel of the upper face is melted, the action of it on a plate, while hot, should change its curvature; upon which account both faces are enamelled at one and the same time.

"The enamel is first put on the concave or under face, which is done, as has been just said, with the fine settlings obtained in washing the granular enamel. For this purpose, a tool is put into the centre hole, and the water being poured off the settlings, it is taken up with a steel spatula, and spread as equally and as thin as possible over the concave surface; the tool is then taken out, and there is put in its place a bit of clean linen, which draws and absorbs the water; if this precaution were not taken, the counter-enamalling would fall off when the dial-plate was turned over.

"To enamel the convex face the plate is turned over, a tool put in the centre hole, and there is spread over the whole surface a layer of the bruised enamel, as evenly as possible, taking care to cover well the edges of the dial-plate, and those of the various holes, to prevent the heat from burning them. To draw off the water which adheres to the enamel, a piece of fine linen is put round the edge of the plate, which draws out nearly all the moisture; and, in order that the particles of the enamel may arrange themselves properly, and be packed as close as possible, a few slight strokes are given to the tool in the centre hole. The neatness with which this is executed is essential; for to this is owing the beauty, polish, and glassy surface of the dial-plate, by reason that the enamel becoming well packed, there are, when it melts, no hollows below the surface, and hence the surface remains perfectly smooth. In order to be sure that no water remains in the enamel, the dial-plates are dried upon a square sheet of iron turned up on the edges on three sides, and placed over a chafing-dish, where it has its temperature raised.

"The preparation of the dial-plate being finished, it is introduced by degrees under a muffle placed in a furnace, in order that it may be heated gradually. The furnace used in London for this purpose has some peculiarities in its construction: but any muffle furnace, if it be well made, will suffice for the purpose. It is left in this state, until the enamel is perceived to begin to melt, when the sheet of iron, on which the plate is placed, is turned round very gently, in order that the heat may effect every part of the dial-plate equally. When the polish of the surface shows that the enamel is melted, the plate is slowly withdrawn from the furnace, and left for some time at the mouth of the muffle, in order that the enamel may cool very slowly, as otherwise it would crack and split off the plate of copper.

"After the first firing, the plate is again cleaned, as before, with water sharpened with aqua-fortis; and the under surface is examined, and if necessary, retouched with the settlings, as before. A fine layer of enamel is also spread over the convex face, and the plate is again exposed to the fire, with the same precautions as before: a third layer of the finest and whitest enamel is again spread on the upper or convex surface, and fired in the same manner; by which means the dial-plate receives all the beauty of which it is capable.

"The hours and minutes are then enamelled on a convex face with a black, soft enamel, made for this purpose. It is ground very fine, in an agate mortar, with a pestle of the same substance, along with oil of spike, and spirit of turpentine. It is considered necessary that the enamel should be reduced to an impalpable powder, and therefore a half day is usually employed in grinding a single Troy drachm. More oil of spike is then added, to render it sufficiently thin to flow from the pencil.

"The place where the hour of twelve is to be placed having been marked from the first by a slight touch of the file, the dial-plate is then placed on a flat surface, and, by means of a pair of compasses, with one point blunt, and placed truly on the centre, and with the other bearing a black-lead pencil, the lines between which the hours and minutes are to be placed, are slightly traced on the surface. In order to divide these circles, a protractor with a moveable limb is used, and the place of the hours and minutes traced with black lead: these are then painted, and when thoroughly dry, the dial-plate is again fired in the same manner as before, and is then finished.

"The dial-plates of clocks, when they do not exceed twelve or fifteen inches in diameter are enamelled in the same way; but larger dial-plates are made in separate pieces, generally as many as there are hours on the face, and then joined together."—*Partington's Scientific Gazette.*

ENCAUSTIC PAINTING. Painting in encaustic is executed with the operation of fire. Ancient authors often mention this species of painting, which, if it had been described simply by the word *encaustic*, which signifies *executed by fire*, might be supposed to have been a species of enamel painting. But the expressions *encausto pingere, pictura encaustica, ceris pingere, picturam inurere*, by Pliny and other ancient writers. show that another species of painting is meant. We have but few ancient pictures of this description, and, therefore, the precise manner adopted by the ancients is not completely developed, though many moderns have closely investigated the subject, and described their processes. This species of painting appears to have been practised in the 4th and 5th centuries.

Count Caylus, and M. Bachelier, a painter, were the first of modern times who made experiments in this branch of art, about the year 1749. Pliny, in a passage relating to encaustic painting, distinguishes three species: 1. that in which the artists used a style, and painted on ivory or polished wood (*cestro in ebore*), for which purpose they drew the outlines on a piece of the aforesaid wood or ivory, previously soaked or imbued with some colour; the point of the style or stigma served for this operation, and the broad end to scrape off the small filaments that arose from the outlines: and they continued forming outlines with the point till they were finished. 2. The next manner appears to have been one in which the wax, previously impregnated with colour, was spread over the surface of the picture with the style, and the colours thus prepared were formed into small cylinders for use. By the side of the painter was a brasier for keeping the styles continually hot, with the points of which they laid on the colours when the outlines were finished, and spread them smooth with the broad end; and thus they proceeded till the picture was finished. 3. The third manner of painting was with a pencil, in wax liquefied by fire.

By this method the colours acquired a considerable hardness, and could not be damaged, either by the heat of the sun or the effects of sea water. In this manner ships were painted, with emblems and other pictures, and therefore obtained the name of *ship painting*. Few, of late years, have made more experiments in this mode of painting that an English lady, Mrs. Hooker, who, for her very successful exertions in this branch of the polite arts, was presented with a gold palette by the Society for the Encouragement of Arts, &c. Her account is printed in the 10th volume of the Society's Transactions, for 1792, when she was Miss Emma Jane Greenland. This subject has also been deeply investigated by the Chevalier Lorgna, in a small but valuable tract, called *Un Discorso sulla Cera Punica.*

As the thing chiefly regarded in encaustic painting was the securing of permanence and durability, by the application of fire, the word *encaustic* has been applied, in a very general sense, to other processes, in which both the material and the mode of applying the heat are entirely different from the ancient materials and modes. The word has been used, not only of wax-painting on wood, stone and ivory, but also for painting on earthen vessels, of works in metal, where gold and silver were inlaid, melted, or laid on, and of every thing which was gilt or silvered by fire; which was called *gold* or *silver encaustic.* The moderns have also used the term for painting on porcelain, and work in enamel; and in the same way it was given to the painting on glass of the middle ages, such as is now seen in the windows of some Gothic churches. It is evident, that all these have nothing to do with the wax-painting of the ancients.

Professor Reinagle has a painting of Cleopatra executed in encaustic, which is valued at two thousand pounds.

ENDEMIC. This name is often applied to diseases which attack the inhabitants of a particular district or country, and have their origin in some local cause, as the physical character of the place where they prevail, or in the employments, habits, and mode of living of the people. Every part of the world, every climate, and every country, has its peculiar endemics. Thus the tropical and warm climates are subject to peculiar cutaneous disorders, and eruptions of various kinds, because the constant heat keeps up a strong action of the skin, and draws the humours to the surface of the body. In northern climates, eruptions of the skin occur, but they are of a different kind. Thus in all the north polar countries, especially in Norway, a kind of leprosy, the *radesyge*, is prevalent, arising from the coldness and humidity of the climate, which dispose the skin to such disorders.

Hot and moist countries generate the most violent typhus and putrid fevers; the West Indies and some of the American seaports, for instance, produce the yellow fever. Places in a more dry and elevated situation, northern countries particularly, are peculiarly subject to inflammatory disorders. In countries and districts very much exposed to currents of wind, especially in mountainous places, we find at all seasons of the year, rheumatisms, catarrhs, and the whole train of complaints which have their origin in a sudden stoppage of the functions of the skin. In large and populous towns, we meet with the most numerous instances of pulmonary consumption. In places that are damp, and at the same time not warm, as in marshes and larger rivers, intermittent fevers are prevalent. In cold and damp countries, like England, Sweden, and Holland, the most frequent cases of croup occur. Diseases which are endemic in one country, may also appear in others, and become epidemical, if the weather and other physical influences resemble those which are the causes of the endemic in the former place; the climate being for a time transferred, as it were, from one to the other. Thus, for instance, we find the croup sometimes, during wet and cold weather, appearing in high situations; intermittent fevers sometimes in places where they occur rarely for years, and then again attack great numbers; putrid and malignant typhus fevers rage in all countries occasionally; and so of the rest.

Endemic disorders, in some circumstances, become contagious, and thereby spread to other persons, and may be transplanted to other places, the situation and circumstances of which predispose them to receive these disorders. This is known by the sad experience of the migrations of diseases, the spreading of the leprosy from the Oriental countries to Europe, &c.

It is useful to inquire into the endemical circumstances of countries, districts, and even cities and towns; some precautions may be thereby suggested to escape the sickness, or to obviate the unwholesomeness of the situation of the place in question. As, for instance, the physician of Pope Clement XI. Lancini, procured the draining and drying of the marshes about Pesaro; and the diseases which had arisen from the exhalations of these marshes immediately ceased. It is also very favourable to the cure of obstinate disorders, for the invalid to remove to a climate opposed to his particular complaint.

Enfilade, in the *military* art, is used in speaking of trenches or positions, which may be scoured by the enemy's shot along their whole length. In conducting the approaches at a siege, care must be taken that the trenches be not enfiladed from any work of the place. In the celebrated battle of Zorndorf, a shot from a Prussian battery, enfilading a Russian square, killed or disabled 30 men.

Engine; a combination of machinery fitted to perform various mechanical offices. Engineering has now become a very important civil profession; and amongst military men they hold the highest station in the army. The commercial importance of the steam engine warrants our giving it a distinguishing feature under that head, when we purpose furnishing a complete account of the various modes of employing elastic vapour in the construction of steam engines. Water engines will be examined under Hydrostatics and Hydraulics.

Engraving is the art of representing, by means of lines and points produced on a metallic surface by cutting or corrosion, the figures, lights, and shades of objects, in order to multiply them by means of printing. The engraver is to the painter what the translator is to the author. As it is impossible to give a spirited translation of a work of genius without a portion of the author's fire, so it is essential to a good engraver that he should feel and understand the character of his original, and be initiated into the secrets of drawing, that his copy may be at once correct and spirited.

The art of engraving on copper was invented in Europe in the first half of the 15th century. The Chinese seem to have been acquainted with it long before. The Dutch, the Italians, and the Germans compete for the honour of its invention in Europe.—It is known that the art was exercised by the Italian Finiguerra as early as 1460. The inventors of it were the goldsmiths, who were in the habit of making devices on their wares; and these, being often executed with much elegance, excited the desire to multiply copies by transferring them to paper. Engraving differs from printing in having its subjects cut into a hard surface, instead of being raised above it, as is the case with types and wood cuts. Many metals and alloys have been employed for the purpose of engraving. The most common is copper, which is soft enough to be cut when cold, and hard enough to resist the action of the press.

We shall now proceed to explain the methods of executing different descriptions of engraving. The graver, an instrument of steel, is principally used in engraving on copper; it is square for cutting of broad lines, and lozenge for the finest, and must be tempered to that exact state, which will prevent the point from breaking or wearing by its action on the metal. The graver is inserted in a handle of hard wood, resembling a pear with a longtitudinal slice cut off, which is to enable the artist to use it as flat on the plate as his fingers and thumb will permit. This instrument is used for removing the imperfections discoverable in etchings, and exclusively in engraving writing. In working, this instrument is held in the palm of the hand, and pushed forward so as to cut out a portion of the copper. The *scraper* is a long, triangular piece of steel, tapering gradually from the handle to the point; the three edges produced by this form, being sharpened on the oil-stone, are used for scraping off the roughness occasioned by the graver, and erasing erroneous lines. The *burnisher* is a third instrument of steel, hard, round, and highly polished, for rubbing out punctures or scratches in the copper. The oil-stone has been already mentioned. To these may be added the needle, or dry point, for etching, and making those extremely fine lines, which cannot be made with the graver. It is held in the fingers in the same way as a pen or pencil. Various kinds of varnish, resin, wax, charcoal, and mineral acids are also employed in different parts of the operation, according to the subject, and the style of engraving which is adopted. The first which we shall describe is

Line Engraving. To trace the design intended for engraving accurately on the plate, it is usual to heat the latter sufficiently to melt white wax, with which it must be covered equally and thin, and suffered to cool; the drawing is then copied in outlines, with a black-lead pencil, on paper, which is laid with the pencilled side upon the wax, and the back rubbed gently with the burnisher, which will transfer the lead to the wax. The design must next be traced, with an etching needle, through the wax on the copper, when, on wiping it clean, it will exhibit all the outlines ready for the graver. The table intended for engraving on should be perfectly steady. Great care is necessary to carry the hand with such steadiness and skill, as to prevent the end of the line from being stronger and deeper than the commencement; and sufficient space must be left between the lines to enable the artist to make those stronger, gradually, which require it.

The roughness or burr occasioned by the graver must be removed by the scraper, the lines filled by the oil-rubber, and the surface of the copper cleansed, in order that the progress of the work may be ascertained. If any accident should occur, by the slipping of the graver beyond the boundary required, or lines are found to be placed erroneously, they are to be effaced by the burnisher, which leaving deep indentings, these must be levelled by the scraper, rubbed with charcoal and water, and finally polished lightly with the burnisher. As the uninterrupted light of the day causes a glare upon the surface of the copper, hurtful and dazzling to the eyes, it is customary to engrave beneath the shade of silk paper, stretched on a square frame, which is placed reclining, towards the room, near the sill of a window. Such are the directions and means to be employed in engraving historical subjects: indeed, the graver is equally necessary for the remedying of imperfections in etching; to which must be added the use of the dry point in both, for making the faintest shades in the sky, architecture, drapery, water, &c., &c.

Stippling. The second mode of engraving is that called *stippling*, or engraving in dots. This resembles the last-mentioned method in its processes, except that, instead of lines, it is finished by minute points or excavations in the copper. These punc-

tures, when made with the dry point, are circular: when made with the graver, they are rhomboidal or triangular. The variations and progressive magnitude of these dots give the whole effect to stippled engraving. This style of work is always more slow, laborious, and, of course, more expensive, than engraving in lines. It has, however, some advantages in the softness and delicacy of its lights and shades, and approaches nearer to the effect of painting than the preceding method. A more expeditious way of multiplying the dots has been contrived in the instrument called a *roulette*, a toothed wheel, fixed to a handle which, by being rolled forcibly along the copper, produces a row of indentations. This method, however, is less manageable than the other, and generally produces a stiff effect.

Engraving of Mezzotintos differs entirely from the manner above described. This method of producing prints which resemble drawings in India ink, is said by Evelyn, in his history of chalcography, to have been discovered by Prince Rupert. Some accounts say that he learned the art from an officer named Siegen, or Sichem, in the service of Hesse-Cassel. It was, some years past, a very favourite way of engraving portraits and historical subjects; of the former, the large heads of Fry are of superior excellence. The tools required for this easy and rapid mode of proceeding are, the grounding-tool, the scraper, and the burnisher.

The copper-plate should be prepared as if intended for the graver, and laid flat upon a table, with a piece of flannel spread under it, to prevent the plate from slipping; the grounding-tool is then held perpendicularly on it, and rocked with moderate pressure backwards and forwards, till the teeth of the tool have equally and regularly marked the copper from side to side; the operation is afterwards repeated from end to end, and from each corner to the opposite; but it is necessary to observe, that the tool must never be permitted to cut twice in the same place; by this means the surface is converted into a rough chaos of intersections, which, if covered with ink and printed, would present a perfectly black impression upon the paper. This is the most tedious part of the process. The rest, to a skilful artist, is much easier than line engraving or stippling. It consists in pressing down or rubbing out the roughness of the plate, by means of the burnisher and scraper, to the extent of the intended figure, obliterating the ground for lights, and leaving it for shades. Where a strong light is required, the whole ground is erased. For a medium light, it is moderately burnished, or partially erased. For the deepest shades, the ground is left entire.

Care is taken to preserve the insensible gradations of light and shade, upon which the effect and harmony of the piece essentially depend. Engraving in mezzotinto approaches more nearly to the effect of oil-paintings than any other species. It is well calculated for the representation of obscure pieces, such as night scenes, &c. The principal objection to the method is, that the plates wear out speedily under the press, and, of course, yield a comparatively small number of impressions.

Etching. Of engravings which require the aid of aqua-fortis, the principal is etching. He that would excel in this branch of the arts must be thoroughly acquainted with drawing. The ground used in etching is a combination of asphaltum, gum mastic, and virgin wax. The proportions of the ingredients should be obtained by experiment. The copper-plate is hammered to a considerable degree of hardness, polished as if intended for the graver, and heated over a charcoal fire; the ground is then rubbed over it, till every part is thinly and equally varnished. The varnish is then blackened by the smoke of a lamp, that the operator may see the progress and state of his work. The next object is to transfer the design to the ground, which may be done by drawing it on thin white paper with a black-lead pencil, and having it passed through the copper-plate printer's rolling press; the lead will be conveyed firmly to the ground, which will appear in perfect outlines on removing the paper.

Another method is, to draw the design reversed from the original: rub the back with powdered white chalk, and, laying it on the ground, trace the lines through with a blunt point; this operation requires much precaution, or the point will cut the ground. After the plate is prepared, the operator, supporting his hand on a ruler, begins his drawing, taking care always to reach the copper. Every line must be kept distinct, throughout the plate, and the most distant should be closer and more regular than those in the foreground, and the greater the depth of shade, the broader and deeper must the lines be made. When the etching of the plate is completely finished, the edges of it must be surrounded by a high border of wax, so well secured that water will not penetrate between the plate and it. The best aqua-fortis must then be diluted with water, and poured upon the plate, which undergoes a chemical action wherever it has been laid bare by the needle, while the remainder of the surface is defended by the varnish. The bubbles of fixed air, and the saturated portions of metal, are carefully brushed away with a feather. After the operator thinks the acid has acted long enough, he pours it off, and examines the plate. If the light shades are found to be sufficiently bit in, they are covered with varnish, or *stopped out*. The biting is then continued for the second shades, which are next stopped out: and so on. After the process is completed, the varnish is melted and wiped off, the plate cleaned with oil of turpentine, and any deficiencies in the lines remedied with the graver. As the acid cannot be made to act with perfect regularity, etchings will always be rough in comparison with line engravings. This very circumstance, however, fits etching for the representation of coarse objects in nature, such as trunks of trees, broken ground, &c., especially on a large scale. In landscape engraving, we generally find a mixture of methods, the coarser parts being etched, the more delicate cut with a graver. Letters and written characters are mostly cut, and seldom etched.

Steel Engraving was introduced by Mr. Perkins. The steel plate is softened by being deprived of a part of its carbon; the engraving is then made, and the plate hardened again by the restoration of the carbon. The great advantage of steel plates consists in their hardness, by which they are made to yield an indefinite number of impressions; whereas a copper plate wears out after 2000 or 3000 impressions, and even much sooner if the engraving be fine. An engraving on a steel plate may be transferred, in relief, to a softened steel cylinder by pressure; this cylinder, after being hardened, may again tranfer the design, by being rolled upon a fresh steel plate; thus

the design may be multiplied at pleasure. Steel plates may also be etched.

Engraving on precious Stones is accomplished with the diamond or emery. The diamond possesses the peculiar property of resisting every body in nature, and, though the hardest of all stones, it may be cut by a part of itself, and polished by its own particles. In order to render this splendid substance fit to perform the operations of the tool, two rough diamonds are cemented to the ends of the same number of sticks, and rubbed together till the form is obtained for which they are intended; the powder thus produced is preserved, and used for polishing them in a kind of mill furnished with a wheel of iron; the diamond is then secured in a brazen dish, and the dust, mixed with olive-oil, applied; the wheel is set in motion, and the friction occasions the polished surface so necessary to give the lustre due effect. Other stones, as rubies, topazes, and sapphires, are cut into various angles on a wheel of copper; and the material for polishing those is tripoli diluted with water.

A leaden wheel, covered with emery mixed with water, is preferred for the cutting of emeralds, amethysts, hyacinths, agates, granites, &c., &c.; and they are polished on a pewter wheel with tripoli; opal, lapis lazuli, &c., are polished on a wheel made of wood. Contrary to the method used by persons who turn metals, in which the substance to be wrought is fixed in the lathe, turned by it, and the tool held to the substance, the engraver of the crystal, lapis lazuli, &c., fixes his tools in the lathe, and holds the precious stone to them, thus forming vases, or any other shape, by interposing diamond dust mixed with oil, or emery and water, between the tool and the substance, as often as it is dispersed by the rotary motion of the former.

The engraving of armorial bearings, single figures, devices, &c., on any of the above stones, after they are polished, is performed through the means of a small iron wheel, the ends of the axis of which are received within two pieces of iron, in a perpendicular position, that may be closed, or otherwise, as the operation requires; the tools are fixed to one end of the axis, and screwed firm; the stone to be engraved is then held to the tool, the wheel set in motion by the foot, and the figure gradually formed. The material of which the tools are made is generally iron, and sometimes brass: some are flat, like chisels, gouges, ferules, and others have circular heads. After the work is finished, the polishing is done with hair brushes fixed on wheels and tripoli.

Engraving in Wood has been practised for several centuries, and originally with tolerable success; it languished for a great part of the 18th century, but revived towards the close, and is still practised in a manner which reflects credit on the ingenuity of the age. The lines, instead of being cut into the substance, are raised, like the letters of printing types, and printed in the same manner. The wood used for this purpose is box, which is preferred for the hardness and closeness of its texture. The surface must be planed smooth, and the design drawn on it with a black-lead pencil; the graver is then used, the finer excavations from which are intended for white interstices between the black lines produced by leaving the box untouched, and the greatest lights are made by cutting away the wood entirely, of the intended form, length, and breadth; but the deepest shades require no engraving. Much of the beauty of this kind of engraving depends upon the printing. Wood engraving has now attained a very high degree of excellence in this country, so much so, indeed, that the Germans, who were themselves the earliest wood engravers send to this country for cuts. Mr. Bonner is at the head of this walk of art. Wood engravings have this advantage, that they may be inserted in a page of common types, and printed without separate expense. They are very durable, and may be multiplied by the process of stereotyping.

Coloured Engravings. Coloured engravings are variously executed. The most common are printed in black outline, and afterwards painted separately in water-colours. Sometimes a surface is produced by aquatinta, or stippling, and different colours applied in printing to different parts, care being taken to wipe off the colours in opposite directions, that they may not interfere with each other. But the most perfect as well as most elaborate productions, are those which are first printed in colours, and afterwards finished by hand.

Engravers, modern. Among modern nations, the Italians, French, Germans, and English have rivalled each other in producing great works in the department of engraving; but, on the whole, the superiority seems to belong to the Italians and French, at least for the number of their productions; but more particularly for the excellence of their impressions. Many great works, executed in Germany, are sent to Paris to be struck off. In Germany, Frederic von Müller, whose Madonna di S. Sisto is still a jewel in collections, died too early for the art. C. Rahl distinguished himself by his engraving of Fra Bartolomeo's Presentation of Christ in the Temple, and of Raphael's St. Margaret. K. Hess, Reindel, Umer (lately deceased), Leybold, Lutz, and A. Kessler, have produced fine cabinet-pieces. John in Vienna, Kobell in Munich, Barth, Amsler, and Rushweyh in Rome, are distinguished in different branches. Chodowiecki, Bause, Bolt, Clemens, Gmelin, and many others, have contributed much to advance the art of engraving. In general, it may be mentioned as a favourable sign of the times, that all the first artists in Germany apply their talents to great works, whilst the taste for souvenir engravings seems rapidly dying away. Those engravers who have produced the best plates for scientific works, so very important a branch of the art, and those in the department of geography, would deserve to be mentioned, if we had room. France has maintained her early fame, in the art of engraving, down to the most recent times. The engravings of A. Boucher-Desnoyers (for instance, the Madonna di Foligno, La Vierge, dite La Belle Jardinière, Francis I. and Margaret of Navarre, Phædre and Hippolyte, the portrait of the Prince de Benevento) are acknowledged masterpieces. Lignon's St. Cæcilia from Domenichino, his Atala, his portrait of Mademoiselle Mars; Massard's St. Cæcilia of Raphael, and Apollo with the Muses of Giulio Romano; Richomme's Dien's, Girodet's, Gudin's, Audouin's plates, no less magnificently than carefully executed; Jazet's large pieces in aquatinta (for instance, from the paintings of Vernet)—all manifest how rich France is in great engravers. Neither ought we to forget the magnificent literary works, almost constantly published in France, which owe their ornaments to the skill of French engravers.

In the most recent productions of the French engravers, an imitation of the school of Morghen is observable; whilst some young Italian and German artists have aimed at something higher than even Morghen's productions. Since the art of painting has ceased to produce many works worthy of multiplication by the burin of the first engravers, these have occupied themselves chiefly with ancient masterpieces, and engraving has taken a higher station among the fine arts. Morghen, the pupil of Volpato, and those who have followed him, have produced works before unequalled. The Milanese school of engravers, in particular, has reached a degree of perfection, through Anderloni and Longhi, which no other country can probably equal. Longhi's Sposalizio is as yet the greatest production in the art of engraving.

Toschi, of Parma, has acquired immortality by his Entrance of Henry IV. into Paris (from Gérard), in 1826; Schiavone, by his Ascension of the Holy Virgin (from the painting of Titian), which may be called perfect, in regard to its picture-like effect. Bettelini, Bonato, Gandolffi, Garavaglia, Fontana Rosapina, Benoglio, Giberti, Palmerini, Poporati, Pavon (by birth a Spaniard, however), Rainaldi and Rampoldi have produced beautifully finished engravings; and Luigi Rossini and Pinelli have etched scenes full of life. Splendid works, in which typography and chalcography unite their attractions, have appeared at Florence, Venice, Rome, and Milan. But England is richer in such works, as our topography forms a peculiar and very important branch of the productions of the art. Some of these works, however, exhibit an exaggerated delicacy, bordering on affectation; while others neglect details, and betray too much effort for effect. But the productions of Earlom, Pether, Dixon, Green, &c. must not be confounded with the works just referred to. The plates of Raphael's cartoons, in Hampton Court, on which Thomas Holloway and Webber were engaged, are praised as the highest specimens of the art. In these engravings, the masterly etching, which often permits them to allow the etchings themselves to remain, is worthy of admiration. Smith, Middiman, Byrne, James Mason, James and Charles Heath, William Woollet, William Sharp, John Burnet, and John Browne, are known to all collectors. Their works are, comparatively, seldom seen on the European continent, because of their high prices.

What Lasinio is for Italy, Moses aims to be for England, by his delicate sketches: among his other productions are his imitations of Retsch's illustrations of Göthe's Faust. But his copies of foreign masters are often deficient in correctness. Martin, Finden, Robinson, and Rolles deserve mention among distinguished English engravers.

With the Dutch, the burin is, at present, not very successful, if we compare their present artists to the former school of Pontius and Edelinck. But for picturesque etchings and productions by the needle, the skill formerly displayed has been preserved by Troostwyk Van Os, Overbeck, Jansen, Chalon, and others. For more highly finished productions, in which the burin and needle must unite, in order to produce a tone, as in the engravings of Rembrandt's pictures, Claessens and De Frey are acknowledged masters.—What Russia, Denmark, and the Netherlands have produced in this branch, is not unworthy of notice. The engravings of Switzerland, mostly in Aberli's manner, form a class by themselves.

In the United States, engraving has been cultivated with more success than any other department of the fine arts, though it cannot be expected that a country so young, and so distant from the numerous productions of former ages, should rival the great works of the art in Europe. But small engravings, particularly on steel, for souvenirs, have been produced, which may bear comparison with European productions of the kind. Among American engravers, Longacre, Kelly, Durandt, Danforth (now in London), Cheney, Gallaudet, Ellis, Hatch, and others, well deserve to be engaged on subjects of more permanent interest than souvenir engravings.

After the art of engraving in mezzotinto was introduced into England, by Prince Rupert, it was carried to much perfection. John Smith, who lived towards the end of the 17th century, has left more than 500 pieces in this style. He and George White formed a new epoch in the art, which the latter particularly improved, by first etching the plates, whereby they acquired more spirit. Of late years, many artists in England have devoted themselves to this branch: among these are M'Ardell, Honston, Earlom, Pether, Green, Watson, Dickinson, Dixon, Hudson, J. Smith, &c.

Enharmonic, in *music;* the epithet given by the ancient Greeks to that of their three genera, which consisted of quarter tones and major thirds. They, however, had originally another kind of enharmonic, more simple and easier of execution than this, and upon which the quarter tones or dieses were considered, by the theorists of the old school, as innovations too refined and artificial.

Ensemble. This term is used in the fine arts to denote the general effect of a whole work, without reference to the parts. Thus we speak of the *ensemble* of a picture, when we consider the effect of the whole representation on the mind of the spectator.—A thing may be excellent in its parts, as, for instance, a comedy, if the different characters are well drawn; yet it may be deficient in its *ensemble,* that is, as a whole. Rousseau uses this word, in the same meaning, in music; but, at present, *ensemble* is used for a composition of several voices, in which the chief voices are independent of each other, as the quintetts and finales in operas and oratorios.

Ensign. *Ensign-bearer,* commonly called *ensign,* is the lowest commissioned officer in the English army. In the French army under Napoleon, the oldest and most distinguished serjeants bore the colours. Napoleon ordered that those serjeants who could not write, and who had distinguished themselves, should be preferred, "because they could not be properly promoted farther, and yet deserved some distinction on account of their bravery." (See *Las Cases*).—In naval language, *ensign* is a large standard or banner, hoisted on a long pole, erected over the poop, and called the *ensign-staff.* It is more commonly called *flag.*

Entablature. In those buildings which are provided with columns, the entablature forms a continuous line immediately above the capitals, and it is frequently made the vehicle for very highly enriched ornaments.

Enteritis; inflammation of the intestines. It is known by the presence of fever, fixed pain in the abdomen, costiveness, and vomiting. The causes are acrid substances, indurated fæces, long-continued and obstinate costiveness, spasmodic cholic, and a stran-

gulation of any part of the intestinal canal; but another very general cause is, the application of cold to the lower extremities, or to the belly itself. It is a disease which is most apt to occur at an advanced period of life, and is very liable to a relapse. It comes on with an acute pain, extending, in general over the whole of the abdomen, but more especially round the navel, accompanied with eructations, sickness at the stomach, a vomiting of bilious matter, obstinate costiveness, thirst, heat, great anxiety, and a quick and hard, small pulse. After a short time, the pain becomes more severe, the bowels seem drawn together by a kind of spasm, the whole region of the abdomen is highly painful to the touch, and seems drawn together in lumpy contractions; invincible costiveness prevails, and the urine is voided with great difficulty and pain. The inflammation continuing to proceed with violence, terminates at last in gangrene; or, abating gradually, it goes off by resolution.

Enteritis is always attended with considerable danger, as it often terminates in gangrene, in the space of a few hours from its commencement. The treatment must be begun by taking blood freely from the arm, as far as the strength of the patient will allow; but, the disease occurring more frequently in persons rather advanced in years, and of a constitution somewhat impaired, it becomes more important to limit this evacuation, and rely, in a great measure, on the effects of a number of leeches applied to the abdomen. Another very useful step is, to put the patient into a hot bath, which may presently induce faintness; or, where this cannot be procured, fomenting the abdomen assiduously. When the symptoms are thus materially relieved, an ample blister should be applied. It becomes also, of the first importance to clear out the bowels. After the disease is removed, care should be taken to guard against accumulation of fæces, exposure to cold, or any thing else likely to occasion a relapse.

Epacts, in *chronology;* the excesses of the solar month above the lunar synodical month, and of the solar year above the lunar year of twelve synodical months; or of several solar months above as many synodical months, and several solar years above as many dozen of synodical months. The epacts, then, are either *annual* or *menstrual.*

Menstrual Epacts are the excesses of the civil or calendar month above the lunar month. Suppose, for example, it were new moon on the first day of January; since the lunar month is 29 days, 12 hours, 44 minutes, 3 seconds, and the month of January contains 31 days, the menstrual epact is 1 day, 11 hours, 15 minutes, 57 seconds.

Annual Epacts are the excesses of the solar year above the lunar. Hence, as the Julian solar year is 365 days, 6 hours, and the Julian lunar year 354 days, 8 hours, 48 minutes, 38 seconds, the annual epact will be 10 days, 21 hours, 11 minutes, 22 seconds, that is, nearly 11 days. Consequently, the epact of 2 years is 22 days; of 3 years, 33 days, or rather 30, since 30 days make an embolismic or intercalary month. Thus the epact of 4 years is 14 days, and so of the rest; and thus, every 19th year, the epact becomes 30, or 0; consequently, the 20th year, the epact is 11 again; and so the cycle of epacts expires with the golden number, or lunar cycle of 19 years, and begins with the same; these are Julian epacts: the Gregorian depend upon the same principles, allowing only for the difference of the respective years. As the new moons are the same, that is, as they fall on the same day after every 19 years, so the difference between the lunar and solar years is the same after every 19 years. And, because the said difference is always to be added to the lunar year, in order to adjust or make it equal to the solar year, therefore the said difference respectively belonging to each year of the moon's cycle, is called the *epact* of the said year, that is, the number to be added to the same year, to make it equal to the solar year.

Rule to find the Gregorian Epact. The difference between the Julian and Gregorian years being equal to the difference between the solar and lunar year, or 11 days, therefore the Gregorian epact for any year is the same with the Julian epact for the preceding year; and hence the Gregorian epact will be found by subtracting 1 from the golden number, multiplying the remainder by 11, and rejecting the 30's. This rule will serve till the year 1900; but, after that year, the Gregorian epact will be found by this rule: Divide the centuries of the given year by 4, multiply the remainder by 17; then to this product add 43 times the quotient, and also the number 86, and divide the whole sum by 25, reserving the quotient: next multiply the golden number by 11, and from the product subtract the reserved quotient, and the remainder, after rejecting all the 30's contained in it will be the epact sought. The following table contains the golden numbers, with their corresponding epacts, till the year 1900.

Table of Gregorian Epacts.

Golden Number	Epacts.	Golden Number.	Epacts.	Golden Number.	Epacts.
I.	0	VIII.	17	XV.	4
II.	11	IX.	28	XVI.	15
III.	22	X.	9	XVII.	26
IV.	3	XI.	20	XVIII.	7
V.	14	XII.	1	XIX.	18
VI.	25	XIII.	12	I.	0
VII.	6	XIV.	23		

Epaulement, in *fortification*, is a kind of breastwork, to cover the troops in front, and sometimes in flank. This term is frequently used for any work thrown up to defend the flank of a post, or any other place.

Epaulette (the French diminutive of *epaule*, shoulder) signifies a military ornament, worn on the shoulder. It originated in the time of Louis XIV. from the riband by which the belt sustaining the sword was kept from slipping from the shoulder. In some armies, every officer wears them, as in the Prussian; but there is a sufficient difference between those worn by different ranks, to enable a lieutenant or a captain to be distinguished immediately from a major or a colonel, and these again from the generals—a circumstance sometimes of great importance in battles. This means of distinction has this advantage, that it is not obvious to the enemy, as white plumes, &c., are. In the Russian and Prussian armies, every officer has two epaulettes; in the French army, this is not the case, but the shoulder on which the epaulette is worn distinguishes a captain or lieutenant. Many troops in the French

service wear woollen epaulettes; for instance, the grenadiers; and Napoleon thought them an efficient protection of the shoulder against the blows of swords. Many of his cavalry and infantry had epaulettes. Epaulettes have been introduced into the English navy, and, in our service, the following are the gradations of rank, as distinguished by them. Masters and commanders have one epaulette on the left shoulder; post-captains, under three years, one epaulette on the right shoulder, afterwards two epaulettes; rear-admirals have one star on the strap of the epaulette, vice-admirals two stars, and admirals three stars. Epaulettes are also worn by many civil officers on the continent of Europe, when in uniform.

EPHEMERIDES, in *astronomy;* tables calculated by astronomers, showing the present state of the heavens, for every day at noon; that is, the places wherein all the planets are found at that time. It is from these tables that the eclipses, conjunctions, and aspects of the planets are determined, horoscopes or celestial schemes constructed, &c.

EPICYCLE, in the ancient astronomy, was a subordinate orbit or circle, which was supposed to move on the circumference of a larger one, called the *different;* by means of which one motion, apparently irregular, was resolved into two that were circular and uniform. And, when the observed motion was so irregular and complicated as not to be resolved with one epicycle, others were added, till a nearer approximation was obtained. This system owed its origin to a prejudice that seems to have been extremely ancient, in favour of circular motion; and the problem that principally engaged the attention of astronomers, in those times, was to assign the proper proportion of the different and epicycle which should approximate nearest to absolute observation.

EPICYCLOID, in *geometry*, is a curve generated by a point in one circle which revolves about another circle, either on the concavity or convexity of its circumference, and thus differs from the common cycloid, which is generated by the revolution of a circle along a right line; though the latter has sometimes been assimilated with the former, by considering the right line as the circumference of a circle the diameter of which is infinite. The invention of epicycloids is ascribed to M. Roemer, the celebrated Danish astronomer.

EPIDEMIC, or EPIDEMIC DISEASE, signifies a state of sickness which prevails in a place or tract of country only for a temporary period. An epidemic always originates in transient external influences, which gradually produce such changes in the bodily system, as finally bring on the sickness. Thus many diseases appear to arise from some peculiar morbid matter in the atmosphere, brought by particular winds; e. g., the influenza, and other diseases: also poor or scanty food, unwholesome mixtures, &c., may occasion epidemics.

Seasons of scarcity, which compel men to have recourse to unusual means of subsistence (as, for example, in Norway and Sweden, to the bark of trees instead of corn), often occasion epidemics. The ergot in rye is supposed to be the cause of *raphania.* Bad barley, or much mixture of bearded darnel (*lolium temulentum*), makes the beer which is prepared from it unwholesome, and produces sickness in those who partake of it. Causes producing a disturbed state of mind, such as war, sieges, earthquakes, &c., by their effects on the nervous system, may very much favour the production of epidemic diseases, or, at least, render them more malignant.

Epidemics sometimes begin with a few, sometimes attack great numbers at once, as commonly happens in a great and sudden change of wind or weather. If, for instance, after a long continuance of a west or south-west wind, with warm weather, it suddenly changes to an east or north-east wind, we hear people complaining directly of coughs, colds, rheumatisms, &c. An epidemic, at its commencement, is usually mild, and becomes more dangerous as it spreads; as it goes off, it for the most part assumes a mild character again. It frequently terminates as gradually as it began, but sometimes suddenly. Many persons are not at all affected by the prevailing epidemic. The cause probably lies in their bodily habit, which is opposed to the prevailing influences, and makes them capable of resisting them longer than other persons. Thus it often happens that men with chronic complaints, hypochondriacs, &c., remain free from epidemic disorders.

Epidemics are often confounded with contagious disorders. The former originally are not contagious; their origin and propagation depend on general influences, and they commonly generate no contagious matter, producing the same disease in another body by contact with it. It is only in particular circumstances, especially if the disorder is a violent one and many patients are crowded into a narrow room, that a contagious matter can be generated, forming a corrupt atmosphere about the sick, and capable of exciting the disease in persons who come near it. Even under these circumstances, contagion does not necessarily take place, and the ignorant generally conceive a hasty and groundless fear of contagion. Thus, for instance, that is frequently ascribed to contagion which is only the consequence of a violent shock of the nervous system at the sight of a sick person, perhaps in a loathsome state, whereby the disease, to which the body was already disposed, is more quickly developed.

EPIDERMIS; the scarf-skin.

EPIGASTRIC. That part of the abdomen that lies over the stomach is called the *epigastric region.* It reaches from the pit of the stomach to an imaginary line above the navel, supposed to be drawn from one extremity of the last of the false ribs to the other.

EPIGLOTTIS; the cartilage at the root of the tongue that falls upon the glottis, or superior opening of the larynx; upper part of the windpipe. Its figure is nearly oval; it is concave posteriorly and convex anteriorly. Its apex or superior extremity is loose, and is always elevated upwards by its own elasticity. While the back of the tongue is drawn backwards in swallowing, the epiglottis is put over the aperture of the larynx; hence it shuts up the passage from the mouth into the larynx. The base of the epiglottis is fixed to the thyroid cartilage, the os hyoides, and the base of the tongue, by a strong ligament.

EPILEPSY; a nervous disease, depending on various causes, often exceedingly complicated, and incapable of being removed; hence so often an incurable periodical disease, appearing in single paroxysms. It, for the most part, is preceded by a cold vapour creeping up from the foot or hand to the breast and head; but sometimes there are no precursive symptoms. The patient suddenly falls, commonly with a cry, the thumbs are convulsed, other parts are agitated more or less entire insensibility succeeds, the breath is

short and quick, broken, and accompanied with groans, the mouth foams, the face is convulsed, the teeth gnash together, the eyes are distorted, the urine and other evacuations are discharged involuntarily, the eyes are wide open and staring, and insensible to the light. The paroxysm is usually over in ten or twenty minutes. The patient awakes as from a deep sleep, entirely unconscious of what has passed; he feels nothing unpleasant, except fatigue, and a little pain in his limbs. Sometimes the paroxysms occur nine or ten times in an hour, or oftener; sometimes only once a month, at the change of the moon, or every six months, or at still longer periods. During the paroxysm, all that is to be attended to is to prevent the patient from injuring himself. All other attempts, such as forcing open the thumbs, and the like, are of no avail, except to terminate the paroxysm sooner, but, at the same time, occasion a quicker return of it, and render the disease more difficult to cure.

Eprouvette; the name of an instrument for ascertaining the strength of fired gunpowder, or for comparing the strength of different kinds of gunpowder. One of the best, for the proof of powder in artillery, is that contrived by Dr. Hutton. It consists of a small brass gun, about 2½ feet long, suspended by a metallic stem, or rod, turning by an axis on a firm and strong frame, by means of which the piece oscillates in a circular arch. A little below the axis, the stem divides into two branches, reaching down to the gun, to which the lower ends of the branches are fixed, the one near the muzzle, the other near the breech of the piece. The upper end of the stem is firmly attached to the axis, which turns very freely by its extremities in the sockets of the supporting frame, by which means the gun and stem vibrate together in a vertical plane, with a very small degree of friction. The piece is charged with a small quantity of powder (usually about two ounces), without any ball, and then fired; by the force of the explosion the piece is made to recoil or vibrate, describing an arch or angle, which will be greater or less according to the quantity or strength of the powder.

Epsom Salt (sulphate of magnesia, cathartic salt) appears in capillary fibres or acicular crystals; sometimes presents prismatic crystals. The fibres are sometimes collected into masses; and it also occurs in a loose, mealy powder; its colour is white, grayish, or yellowish; it is transparent, or translucent, with a saltish, bitter taste. It is soluble in its own weight of cold water, and effloresces on exposure to the air. It is composed of water, sulphuric acid, and magnesia. It is found covering the crevices of rocks, in caverns, old pits, &c., in the vicinity of Jena, on the Harz, in Bohemia, &c., in mineral springs, in several lakes in Asia, and in sea-water. It is obtained for use from these sources, or by artificial processes, and is employed in medicine as a purgative. The English name is derived from the circumstance of its having been first procured from the mineral waters at Epsom. A person of the name of Grisenthwaite has taken out a patent for this medicine. The new process by which Epsom salts are to be produced is by mixing together magnesia, sulphate of lime, or plaster of Paris, with carbonic acid and water, which will form a sulphate of magnesia. The magnesia is to be obtained either by precipitation from sea-water, or by the common earthy precipitations, or from the magnesian limestone. The same modes of evaporation and crystallization are to be employed as are usually practised by chemists. The patentee claims to be the first who has used sulphate of lime, and carbonic acid, for the production of the above salt. (See Magnesia.)

Equation, in *algebra*, is the expression of the equality of different indications of the same magnitude; as, for instance, 9 and 2 are equal to 11, in mathematical characters is expressed thus:—$9+2=11$; or, 3 from 4 leave 1, is $4-3=1$. An equation may contain known quantites and unknown quantities. The latter are usually indicated by the last letters of the alphabet; and it is one of the main objects of mathematics to reduce all questions to equations, and to find the value of the unknown quantities by the known, which is sometimes a difficult, but, at the same time, interesting operation; because x, or the unknown quantity, may be given under so involved a form as to require the greatest tact to determine its value. The work of Meier Hirsch, already mentioned in a previous article is, perhaps, the best collection of equations for solution. There must always be as many equations as there are unknown quantities; and it is not always easy to form these from the question proposed. The equation is called *simple, quadratic, cubic, bicubic, of the fifth*, &c. *degree*, according to the exponent of the unknown quantity; for instance $(x^2-4cdy+xp)\,x^4=pq-\sin 4p$, is an equation of the sixth degree.

Equation of Payments, in *arithmetic*, is the finding the time to pay at once several debts due at different times, and bearing no interest till after the time of payment, so that no loss shall be sustained by either party. The rule commonly given for this purpose is as follows:—Multiply each sum by the time at which it is due; then divide the sum of the products by the sum of the payments, and the quotient will be the time required. Thus, for example, A owes B 190*l*., to be paid as follows; viz. 50*l*. at 6 months, 60*l*. at 7 months, and 80*l*. at 10 months: what is the equated time at which the whole ought to be paid, that no loss may arise, either to debtor or creditor? By the rule,

$$\begin{array}{rl} 50 \times 6 = & 300 \\ 60 \times 7 = & 420 \\ 80 \times 10 = & 800 \\ \hline 190 \quad) & 1520 \ (8 \text{ months, equat.} \\ & 1520 \quad \text{time.} \end{array}$$

This rule, however, is founded on a supposition that the interest of the several debts which are payable before the equated time, from their terms to that time, ought to be equal to the sum of the interest of the debts payable after the equated time, from that time to their terms respectively, which, however, is not correct, as it is the discount that is to be considered, and not the interest, in the latter sums. In most cases, however, that occur in business, the error is so trifling, that the popular rule will probably always be made use of, as being by far the most eligible and expeditious method that we could suggest.

Equation of Time, in *astronomy*, derotes the difference between mean and apparent time, or the reduction of the apparent unequal time, or motion of the sun or a planet, to equable and mean time or motion. If the earth had only a diurnal motion, without an annual, any given meridian would revolve from the sun to the sun again in the same space of time as from any star to the same star again,

because the sun would never change his place with respect to the stars. But as the earth advances almost a degree eastward in its orbit in the time that it turns eastward round its axis, whatever star passes over the meridian on any day with the sun, will pass over the same meridian on the next day, when the sun is almost a degree short of it, that is, 3 minutes, 56 seconds sooner. If the year contained only 360 days, as the ecliptic does 360 degrees, the sun's apparent place, so far as his motion is equable, would change a degree every day, and then the sidereal days would be 4 minutes shorter than the solar. The mean and apparent solar days are never equal, except when the sun's daily motion in right ascension is 59″; which is nearly the case about the 15th of April, the 15th of June, the 1st of September, and 24th of December, when the equator is 0′, or nearly so; and it is at its greatest about the 1st of November, when it is 16′ 14″.

EQUATOR. By the celelestial equator is understood that imaginary great circle in the heavens, the plane of which is perpendicular to the axis of the earth; it is every where 90° distant from the poles of the earth, which are therefore its poles, and its axis is the axis of the earth. It divides the celestial sphere into the northern and southern hemispheres. During his apparent yearly course, the sun is twice in the equator, at the beginning of spring and of autumn. Then the day and night are equal,—whence the name of *equator*. The situation of the stars, with respect to the equator, is determined by their declension and right ascension. The equator, or equinoctial, called by mariners simply the *line*, is that great circle of our globe, every point of which is 90 degrees from the poles, which are also its poles, and its axis is the axis of the earth. It is in the plane of the celestial equator. All places which are on it, have invariably equal days and nights. (See DAY.) Our earth is divided by it into the northern and southern hemispheres. The diurnal revolution of the earth is in the direction of it. It crosses the centre of Africa, the islands of Sumatra, Borneo, Celebes. &c., in Asia, then traverses the Pacific ocean, and crosses South America, in Colombia, thence proceeds through the Atlantic back to Africa. To cross the line, in navigation, is to pass over the equator. The equatorial regions are subject to long calms, alternating with frightful hurricanes.

As equal or mean time is estimated by the passage of arcs of the equator over the meridian, it frequently becomes necessary to convert parts of the equator into time, and the converse, which is performed by the following analogy, viz.—as 15° : 1 hour : : any arc of the equator : the time it has been in passing. Or, conversely, 1 hour : 15° : . any given time : to the arc of the equator.—From this circle is reckoned the latitude of places, both north and south, in degrees of the meridian. (See LATITUDE and LONGITUDE.)

EQUATORIAL, UNIVERSAL, or PORTABLE OBSERVATORY, is an instrument intended to answer a number of useful purposes in practical astronomy, independent of any particular observatory. It may be employed in any steady room or place, for performing many useful problems. (See ASTRONOMY.)

EQUINOCTIAL, in *astronomy;* a great circle of the sphere, under which the equator moves in its diurnal motion. It is the same as the *celestial equator.* (See EQUATOR.)

EQUINOCTIAL GALES; storms which are observed generally to take place about the time of the sun's crossing the equator or equinoctial line, at which time there is equal day and night throughout the world.

EQUINOCTIAL POINTS are the two points wherein the equator and ecliptic intersect each other: the one, being in the first point of Aries, is called the *vernal* point; and the other, in the first point of Libra, the *autumnal* point.

EQUINOX is that time of the year when the day and night are equal: the length of the day is then 12 hours; the sun is ascending 6 hours, and descending the same time. This is the case twice a year, in the spring and in autumn, when the sun is on the equator. When the sun is in this situation, the horizon of every place is, of course, divided into two equal parts by the circle bounding light and darkness; hence the sun is visible every where 12 hours, and invisible for the same time in each 24 hours. (See DAY.) The vernal equinox marks the beginning of spring, the autumnal that of autumn: at all other times, the lengths of the day and of the night are unequal, and their difference is the greater the more we approach either pole, and in the same latitude it is every where the same. Under the line, this inequality entirely vanishes: there, during the day, which is equal to the night, the sun always ascends 6 hours, and descends 6 hours. In the opposite hemisphere of our earth, the inequality of the days increases in proportion to the latitude: the days increase there, while they diminish with us, and *vice versâ*. The points where the ecliptic comes in contact with the equator are called *equinoctial* points.

The vernal equinoctial point was formerly at the entrance of the constellation of Aries; hence the next 30 degrees of the ecliptic, reckoned eastward from it, have been called *Aries;* but this point long ago deserted the constellation of Aries, and now stands under Pisces; for it is found by observation, that the equinoctial points of the ecliptic are continually moving backward, or westward; which retrograde motion of the equinoctial points is what is called the *precession of the equinoxes*. (See PRECESSION.) It appears from the result of calculations, that the path of either of the poles is a circle, the poles of which coincide with those of the ecliptic, and that the pole will move along that circle so slowly as to accomplish the whole revolution in about 25,791 years, nearly. The diameter of this circle is equal to twice the inclination of the ecliptic to the equator, or about 47 degrees. Now, as the ecliptic is a fixed circle in the heavens, but the equator, which must be equidistant from the poles, moves with the poles, therefore the equator must be constantly changing its intersection with the ecliptic. And from the best observations, it appears, that the equator cuts the ecliptic every year 50 seconds .25, more to the westward than it did the year before; hence, the sun's arrival at the equinoctial point precedes its arrival at the same fixed point of the heavens every year, by 20 minutes 23 seconds of time, or by an arc of 50 seconds .25.—Thus, by little and little, these equinoctial points will cut the ecliptic more and more to the westward, till, after 25,791 years, they return to the same point.

ERGOT is an important article in *materia medica;* has been found capable of exerting a very powerful

and specific action upon the uterus, and is administered in small doses in certain extreme cases.

Ermine, in *commerce;* a species of fur which produces a very high price. The finest comes from Asia, and a dress frequently costs from one to two hundred pounds.

Eruption, in *medicine;* a sudden and copious excretion of humours, and the same with *exanthema*, or breaking out; as the pustules of the plague, small-pox, measles, &c.

Erysipelas. This disease is an inflammatory affection, principally of the skin, when it makes its appearance externally, and of the mucous membrane, when it is seated internally; and is more liable to attack women and children, and those of an irritable habit, than those of a plethoric and robust constitution. Erysipelas sometimes returns periodically, attacking the patient once or twice a year, or even once every month; and then, by its repeated attacks, it often gradually exhausts the strength, especially if the patient be old and of a bad habit. Every part of the body is equally liable to it; but it more frequently appears on the face, legs, and feet, than any where else, when seated externally. It is brought on by all the causes that are apt to excite inflammation, such as injuries of all kinds, the external application of stimulants, exposure to cold, and obstructed perspiration; and it may likewise be occasioned by a certain matter generated within the body, and thrown out on its surface. A particular state of the atmosphere seems sometimes to render it epidemical. A species of erysipelatous inflammation, which most usually attacks the trunk of the body, is that vulgarly known by the name of *shingles*, being a corruption of the French word *ceingle*, which implies a belt. Instead of appearing a uniform inflamed surface, it consists of a number of little pimples extending round the body a little above the *umbilicus*, which have vesicles formed on them in a short time. Little or no danger ever attends this species of erysipelas.

Escalade, in *war;* a furious attack of a wall or a rampart, carried on with ladders, to pass the ditch or mount the rampart, without proceeding in form, breaking ground, or carrying on regular works to secure the men.

Escapement; that portion of a clock which, by giving motion to the pendulum, serves to regulate the operations of the wheel-work. It consists of the pallets, swing-wheel, and crutch: the latter connects the escapement with the pendulum. Under the article Watch, the various species of escapement belonging to that machine will be described.

Escutcheon, in *heraldry*, is derived from the the French *écusson*, and that from the Latin *scutum*. It signifies the shield whereon coats of arms are represented.

Esplanade, in *fortification;* the sloping of the parapet of the covered way towards the open country; the same with *glacis*.

Esquire; anciently, the person that attended a knight in the time of war, and carried his shield. Those to whom the title of *esquire* is now due in England, are, all noblemen's younger sons, and the eldest sons of such younger sons; the eldest sons of knights, and their eldest sons; the officers of the king's court, and of his household; counsellors at law, justices of the peace, &c., though the latter are only esquires in reputation: besides, a justice of the peace holds this title no longer than he is in commission, in case he is not otherwise qualified to bear it; but a sheriff of a county, who is a superior officer, retains the title of *esquire* during life, in consequence of the trust once reposed in him. The heads of some ancient families are esquires by right of prescription.

Essential Oils. This name is applied to those volatile fluids usually obtained from aromatic plants, by subjecting them to distillation with water. The oil is volatilized with the aqueous vapour, and is easily condensed; a small portion of it is retained in solution by the water; but the greater part separates, and is obtained pure from the difference in their specific gravity. In some instances, as, for example, in the rind of the orange and lemon, the oil exists in distinct vesicles, and may be obtained by expression.

The principal volatile or essential oils are those of turpentine, aniseed, nutmeg, lavender, cloves, caraway, peppermint, spearmint, sassafras, camomile, and citron. The taste of those oils is acrid and burning; and their odour very pungent, generally resembling the taste and smell of the vegetables affording them. They are generally fluid, and remain so even at a low temperature; but some congeal at a very moderate degree of cold, and others are naturally concrete. They are extremely volatile, and boil at a temperature considerably above that of boiling water; thus oil of turpentine boils at 315°. They are very soluble in strong alcohol, but, on adding water largely, are precipitated. They are soluble in ether in like manner, but do not form soaps with the alkalies, by which they are distinguished from the fixed oils. They are readily inflamed by strong nitric acid; especially with the precaution of adding a little sulphuric acid to render the former more concentrated. Exposed to the action of the air, they undergo an alteration in consequence of the absorption of oxygen, become thickened, and gradually change into a solid matter, resembling the true resins. When digested with sulphur, they unite with it, forming what have been called *balsams of sulphur*.

One of the most useful and abundant of the essential oils is that of turpentine, commonly called *spirit of turpentine*. It is obtained by distilling turpentine and water, in due proportions, from a copper alembic. It is perfectly limpid and colourless, has a strong smell, a bitterish taste, boils at 315°, and is extremely inflammable. It is the solvent employed in making a variety of varnishes; but for purposes of nicety, it requires to be rectified by a second distillation. In general, the volatile oils are used in the practice of medicine, or as perfumes. Those applied to the latter use, as the essence of rose, of jasmine, violet, &c., are possessed of a more feeble odour, and, being obtained from the flowers of their respective plants, require much care in their preparation. This is done by spreading upon white wool, impregnated with olive oil, the petals of the flowers, and leaving them for some time, covered over with a woollen cloth, upon which flowers are also scattered. The flowers are renewed from time to time, until the olive oil employed appears to be saturated with the oil of the flowers, when this last is separated by digesting the wool in alcohol.

Ether; a very subtle fluid. As the class of bodies known under this name are of great importance in chemistry, we may notice them somewhat in detail. They differ in their qualities as produced by different acids; but they agree in the possession of certain

general properties; they are highly volatile, odorous, pungent, and inflammable; miscible with water, and capaple of combination with alcohol in every proportion.

Sulphuric ether, produced by the action of sulphuric acid on alcohol, is the one which has been longest known to chemists. To prepare sulphuric ether, sulphuric acid is poured on an equal weight of alcohol in a retort; and, after they are thoroughly mixed by gradual agitation, heat is applied by the medium of a sand-bath, a large receiver being adapted to the retort, carefully luted, and kept cool by water. Distillation commences when the temperature is raised to 208°, and a colourless liquid condenses in the receiver. When it amounts to about half the quantity of alcohol that had been employed, the heat is withdrawn. The residual liquid is of a dark brown or black colour. If a fresh portion of alcohol, not more than half of the first quantity, be added to it when it is cold, an additional portion of ether will be procured by a new distillation.

The ether condensed in the receiver by this process, is weak from the intermixture of water, and is usually also impure from the presence of a portion of sulphurous acid. It is rectified by agitating it with subcarbonate of potash, or muriate of lime, and distilling it a second time by a very gentle heat, putting into the retort from which it is distilled a small quantity of black oxide of manganese.

Sulphuric ether is a fluid extremely light; its specific gravity, when it is highly rectified, being so low as .716. It is colourless and transparent, has a pungent taste, and a penetrating, rather fragrant odour. It is highly volatile, evaporating rapidly at natural temperatures. It boils under the usual atmospheric pressure at 98°, and, *in vacuo*, at a temperature even below 32°. In its spontaneous evaporation, it absorbs a considerabte quantity of caloric, so as to produce much cold. It congeals at 47°. It is inflammable, burns with a clear white flame, and without smoke, producing by its combustion water and carbonic acid. Its vapour, diffused in atmospheric air or oxygen gas, explodes when kindled.

Sulphuric ether is soluble in water, requiring about 10 parts for its solution. It dissolves in alcohol in every proportion. On the fixed alkalies or earths it exerts no action; with ammonia it combines by distillation. It dissolves sulphur and phosphorus in small proportions; and it resembles alcohol in the solvent operation it exerts on a number of the vegetable proximate principles.

Nitric ether is formed by the action of nictric acid on alcohol; but, from the violence of this action, the process is difficult, and requires to be conducted with much caution. Various methods have been employed; that of Woolfe is generally preferred. It consists in adding to four parts of nitre in coarse powder in a retort, a mixture, in successive small portions, of four parts of sulphuric acid, and rather more than three parts of alcohol, connecting the retort with a range of receivers, kept cool; nitric ether is formed and volatilized without the application of heat, and is condensed by passing the gaseous product through water, or through a solution of muriate of soda in the receivers. It floats above the liquor, and is purified from any free acid by agitation with lime, and a second distillation with a gentle heat.

Nitric ether has an odour strong, but less fragrant than that of sulphuric ether; it is light, volatile, and inflammable. When pure and highly rectified, its levity is such that it floats on water; and its volatility is so great that it instantly evaporates when poured from a bottle, and it boils at 70°, under the usual atmospheric pressure; it requires 50 parts of water for its solution, but combines with alcohol in every proportion. (See PHOSPHORIC and MURIATIC ETHER.)

ETCHING ON GLASS. The process of etching as applied to copperplate *engraving*, will be found under that article; but that which is effected by fluoric acid on glass, is so curious as to deserve a particular description. The original invention of this beautiful art appears to belong to the beginning of the last century. In an old German work, entitled *Breslawer's Collections*, is the following notice:—"The discovery of a powerful acid, by means of which every imaginable kind of figures may easily be etched upon glass. Take spiritus nitri per distillationem, put it into a retort, and apply a strong heat. When it has passed over into the receiver, throw into it some powdered green Bohemian emerald (which, when heated, shines in the dark), otherwise called phosphrous.—This being done, place the receiver, containing the mixture, on a heated sand-bath, for about four-and-twenty hours, and it will be fit for the purpose. To use this corrossive acid, take a pane of glass of any kind, clean it well, and free it from grease, by washing it with ley, and, when dry, trace out upon it, with sulphur and varnish, whatever you choose. Put a border of bees-wax round it, about an inch high, and then pour the corrossive acid, prepared as before directed, carefully over the whole surface of the glass, and let it stand undisturbed for some time—the longer the better. The glass will become corroded, and all you have traced before will now appear as if raised or elevated above the surface of the glass, in a very distinct and pleasing manner." (See FLUORIC ACID.)

EUCHLORINE. This gas was discovered in 1811, by Sir H. Davy, and described by him in the *Philosophical Transactions* for that year under this name. It is made by the action of muriatic acid on chlorate of potash; and its production is explicable by the fact, that muriatic and chloric acids mutually decompose each other. When muriatic acid and chlorate of potash are mixed together, part of the muriatic acid unites with the potash of the salt, and thus sets chloric acid free, which instantly re-acts on the free muriatic acid. The result of the re-action depends on the relative quantity of the substances. If chlorate of potash be mixed with excess of concentrated muriatic acid, the chloric acid undergoes complete decomposition. The best proportion of the ingredients is two parts of chlorate of potash, one of strong muriatic acid, and one of water; and the re-action of the materials should be promoted by heat sufficient to produce moderate effervescence. The gases should be collected over mercury, which combines with the chlorine, and leaves the protoxide of chlorine in a pure state. Protoxide of chlorine has a yellowish green colour, similar to that of chlorine, but considerably more brilliant, which induced Sir H. Davy to give it the name of *euchlorine*. Its odour is like that of burnt sugar. Water dissolves eight or ten times its volume of the gas, and acquires a colour approaching to orange. It bleaches vegetable substances, but gives the blue colours a tint of red before destroying them. It does not unite with alkalies, and therefore is not an acid. It is explosive in a high degree. Protoxide of chlorine is easily ana-

lyzed by heating a known quantity of it in a strong tube over mercury. An explosion takes place; and 50 measures of the gas expand to 60 measures, of which 20 are oxygen, about 40 chlorine.

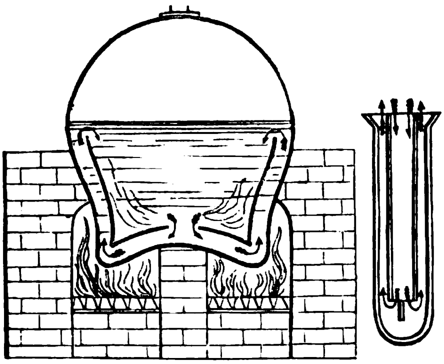
Eudiometer; an instrument for ascertaining the purity of air, or, rather, the quantity of oxygen contained in any given bulk of elastic fluid. Dr. Priestley's discovery of the great readiness with which nitrous gas combines with oxygen, and is precipitated in the form of nitric acid, was the basis upon which he constructed the first instrument of this kind. It consisted of a glass vessel, containing an ounce by measure. This was filled with the air to be examined, which was transferred from it to a jar, of an inch and a half diameter inverted in water; an equal measure of fresh nitrous gas was added to it, and the mixture was allowed to stand two minutes. If the absorption were very considerable, more nitrous gas was was added, till all the oxygen appeared to be absorbed. The residual gas was then transferred into a glass tube, two feet long and one-third of an inch wide, graduated to tenths and hundredths of an ounce measure; and thus the quantity of oxygen absorbed was measured by the diminution that had taken place. Other eudiometrical methods were employed by other chemists. Volta had recourse to the detonation of air with hydrogen gas. For this purpose, two measures of hydrogen gas are introduced into a graduated tube, with three of the air to be examined, and fired by the electric spark. The diminution of bulk observed after the vessel had returned to its original temperature, divided by three, gives the quantity of oxygen consumed. The action of liquor prepared from sulphur and potash, or sulphur and lime, boiled in water, and the slow combustion of phosphorus, have, likewise, been employed in eudiometry. Dobereiner has suggested the use of little balls of spongy platina, for the purpose of detecting minute portions of oxygen in a gaseous mixture, in which hydrogen is also present. Its effect is immediate and complete. The moment the substance rises above the surface of the mercury, in the tube containing the mixture, the combination of the oxygen and hydrogen begins, and in a few minutes is completed. So energetic is it in its action, that it enables hydrogen to take 1 of oxygen from 99 of nitrogen. See the various gases in their alphabetical order.

Evaporation is the conversion of liquid and solid bodies into elastic fluids, by the influence of caloric. Expose, for instance, water to heat, bubbles at first adhere to the sides of the vessel, which, by degrees, ascend to the surface, and burst. These bubbles rise the more rapidly in proportion to the heat. Water is evaporated by the heat of the sun merely, and even without this in the open air, and the vapour, rising into the air, is condensed into clouds. The general cause of evaporation is caloric; but different substances require different degrees of it. Water is particularly subject to evaporation. It evaporates at a very low temperature, and, from the immense quantity which is spread over the earth, it may be inferred, with great probability, that the most important changes in our atmosphere are occasioned by it. Instruments have been invented to measure the evaporation of water (see Hygrometry), but the results are uncertain. If we assume, as experiments justify, that the annual evaporation averages 30 inches (i. e. that the vapour, if reconverted into water, would cover the surface from which the evaporation took place, to a height of 30 inches), then, the surface of all the waters on our earth being assumed at 128,000,000 of geographical miles, 60,000 cubic miles of water would be annually changed into vapour; and the amount will be still greater, if we add to it the evaporation from moist earth and from the watery parts of the vegetable and animal kingdoms. In summer, evaporation is generally much greater than in winter; yet it is not so inconsiderable in cold weather as we might suppose from the small quantity of caloric then sensible. Even in the polar circles, it does not entirely cease; for ice evaporates in the open air. To account for the phenomenon of evaporation, two hypotheses have been formed; that it is a conversion of fluids into elastic vapour by their union with caloric, or that it is a real solution of the fluids in the air. The latter theory has been opposed, particularly by De Luc. He maintains that, in evaporation, water combines with caloric, without being dissolved in the air. The principal argument in support of this theory is, that cold is generated by the evaporation of a liquid. Cold is only the absence or consumption of caloric. If now, in evaporation, caloric is consumed, i. e. is combined with the evaporated water, this consumption must generate a sensible cold. De Luc farther maintains, that the air, so far from contributing to evaporation, prevents it by pressure. If this pressure is removed, the same quantity of water requires far less caloric to evaporate it; for experiments show that water evaporates more rapidly in a vacuum than in the air, and Saussure says, that at the same degree of the thermometer and hygrometer, the evaporation on mountains, where the air is of three times less density, is more than double that in the valleys. Later experiments render it still more evident that a dissolving power of air is not necessary to change water into an elastic vapour, since, otherwise, it could not be produced in a vacuum. Such a dissolving power in the air, however, is absolutely required to effect a uniform mixture of this vapour with air; otherwise, from the difference of the specific gravities of the two fluids, a separation must ensue, of which we have no experience; and we find ourselves compelled to regard the union of the expansive vapour with the air as a true solution of the one in the other. (See Perspiration.)

Artificial Evaporation is a chemical process, usually performed by applying heat to any compound substance, in order to separate the volatile parts. It differs from distillation, its object being chiefly to preserve the more fixed matters, while the volatile substances are allowed to escape. Accordingly, the vessels in which these two operations are performed are different; evaporation being commonly made to take place in open, shallow vessels, and distillation in an apparatus nearly closed from the external air.

There is a most important improvement in the process of artificial evaporation, which must be noticed here. We are indebted to Mr. Perkins for this discovery, which is now in operation on one of the large rail roads, and, as it is the subject of a patent, the apparatus may be thus briefly described: It consists of a boiler furnished with a casing, or inner boiler. On applying fire beneath, the vapour rises, carrying with it a considerable portion of the water. The power of the current to put in motion other bodies is most extraordinary—masses of sand, and even flint stones, are by this means driven along in rapid succession.

The direction of the current is shown in the engraving by that of the arrows.



The same is seen to occur in the case of the tubular boiler shown in the narrow section. Now one of the principal advantages is, that this species of boiler requires less fuel, as all the caloric is at once absorbed by the water. And another, and scarcely less important advantage, is found to arise from the boiler needing no cleaning, as the constant circulation, like that of the veins and arteries in the human body, keeps the whole of the surfaces in a clear state.

EXANTHEMATA; diseases of the skin, joined with fever, hence called *acute*, *hot* eruptions, to distinguish them from *chronical* eruptions, which are only incidentally accompanied with fever (called, in medical language, *impetigines*.) They include the small-pox, measles, scarlet-fever, rash, &c. Each has its peculiarities, relating to the manner of its origin, to the form and position of the eruption, and to the continuance of the disorder. (See SMALL-POX, &c.)

EXCISE DUTY; an impost laid on various commodities as they are consumed in retail. As a great change is promised, and likely to take place in the laws which now place every dealer in exciseable articles under the inquisitorial powers of the servants connected with this branch of the revenue, we purpose entering fully into the subject under TAXATION.

EXPANSION, in *physics*, is the enlargement or increase in the bulk of bodies, in consequence of a change in their temperature. This is one of the most general effects of heat, being common to all bodies whatever, whether solid or fluid. The expansion of solid bodies is determined by the pyrometer, and that of fluids by the thermometer. (See those articles.) The expansion of fluids varies considerably; but, in general, the denser the fluid, the less the expansion; thus water expands more than mercury; and spirits of wine more than water; and, commonly, the greater the heat, the greater the expansion; but this is not universal, for there are cases in which expansion is produced, not by an increase, but by a diminuation of temperature. Water furnishes us with the most remarkable instance of this kind. Its maximum of density corresponds with 42°.5, of Fahrenheit's thermometer; when cooled down below 42°.5 it undergoes an expansion for every degree of temperature which it loses; and at 32°, the expansion amounts to $\frac{1}{160}$ of the whole expansion which water undergoes when heated from 42°.5 to 212°. With this more recent experiments coincide very nearly; for, by cooling 100,000 parts in bulk of water from 42°.5 to 32°, they were converted to 100,031 parts.

The expansion of water is the same for any number of degrees above or below the maximum of density. Thus, if we heat water 10° above 42°.5, it occupies precisely the same bulk as it does when cooled down to 10 degrees below 42°.5. Therefore the density of water at 32° and at 53° is precisely the same. Dalton cooled water to the temperature of 5° without freezing, or 37°.5 below the maximum point of density; and, during the whole of that range, its bulk precisely corresponds with the bulk of water the same number of degrees above 42°.5. The prodigious force with which water expands in the act of freezing, is shown by glass bottles filled with water, which are commonly broken in pieces when the water freezes. A brass globe, whose cavity is an inch in diameter, may be burst by filling it with water and freezing it; and the force necessary for this effect is 27,720 lbs. weight. The expansive force of freezing water may be explained by supposing it the consequence of a tendency which water, in consolidating, is observed to have to arrange its particles in one determinate manner, so as to form prismatic crystals, crossing each other at angles of 60° and 120°. The force with which they arrange themselves in this manner must be enormous, since it enables small quantities of water to overcome so great mechanical pressures. This observation is conspicuously illustrated by observing the crystals of ice on a piece of water exposed to the action of the air in frosty weather; or upon a pane of glass in a window of a room without a fire, at the same season. Various methods have been tried to ascertain the specific gravity of ice at 32°; that which succeeded best was to dilute spirits of wine with water till a mass of solid ice put into it remained in any part of the liquid without sinking or rising. The specific gravity of such a liquid is 0.92, which, of course, is the specific gravity of ice, supposing the specific gravity of water at 60° to be 1. This is an expansion much greater than water experiences even when heated to 212°, its boiling point. We see from this that water, when converted into ice, no longer observes that equable expansion measured by Dalton, but undergoes a very rapid and considerable augmentation of bulk.

EXPECTORANTS, in *pharmacy*; medicines which promote expectoration. Such are the stimulating gums and resins, squills, &c.

EXPECTORATION; the act of evacuating, or bringing up phlegm, or other matters, out of the trachea and lungs, by coughing, &c.

EXPERIMENTAL PHILOSOPHY is that which deduces the laws of nature, the properties and powers of bodies, and their actions upon each other, from sensible experiments and observations. In our inquiries into nature, we are to be guided by those rules and maxims which are found genuine, and consonant to a just method of physical reasoning; and these rules are, by Sir Isaac Newton, reckoned four, viz. First. More causes of natural things are not to be admitted than are true, and sufficient to explain the phenomena; for nature is simple, and does nothing in vain. Second. Therefore, of natural effects of the same kind, the same causes are to be assigned, as far as it can be done; as of respiration in man and beasts, of the descent of stones in Europe and America, of light in a culinary fire and in the sun, and of the reflection of light in the earth and

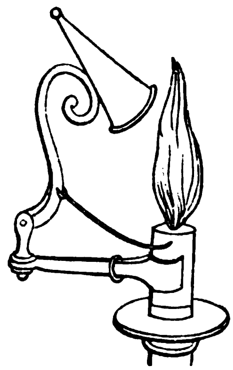
the other planets. Third. The qualities of natural bodies, which cannot be increased or diminished, and agree to all bodies on which experiments can be made, are to be reckoned as the qualities of all bodies whatever; thus, because extension, divisibility, hardness, impenetrability, mobility, the *vis inertiæ*, and gravity, are found in all bodies under our inspection, we may conclude that they belong to all bodies whatever, and are the original and universal properties of them. Fourth. In experimental philosophy, propositions collected from the phenomena by induction, are to be deemed (notwithstanding contrary hypotheses) either exactly, or very nearly true, till other phenomena occur, by which they may be rendered more accurate, or liable to exception. This ought to be done, lest arguments of induction should be destroyed by hypotheses, and logical series be superseded by conjectures.

EXPLOSION, in *natural philosophy;* a sudden and violent expansion of an aërial or other elastic fluid, by which it instantly throws off any obstacle in its way. Explosion differs from expansion in this,—that the latter is a gradual power, acting uniformly for some time, whereas the former is momentary. The expansions of solid substances do not terminate in violent explosions, on account of their slowness, and the small space through which the expanding substance moves. Thus we find, that, though wedges of wood, when wetted, will cleave solid blocks of stone, they never throw them to any distance, as gunpowder does. On the other hand, it is seldom that the expansion of any elastic fluid bursts a solid substance, without throwing the fragments of it to a considerable distance. The reasons of this may be comprised in these particulars: First. The immense velocity with which the aërial fluids expand, when affected by a considerable degree of heat. Second. Their celerity in acquiring heat, and being affected by it, which is much superior to that of solid substances. Thus air, heated as much as iron when brought to a white heat, is expanded to four times its bulk; but the metal itself will not be expanded the 500th part of that space. In the case of gunpowder, the velocity with which the flame moves is calculated, by Mr. Robins, to be no less than 7000 feet in a second, or little less than 70 miles per minute. Hence the impulse of the fluid is inconceivably great, and the obstacles on which it strikes are carried off with vast velocity, though much less than that just mentioned; for a cannon-ball, with the greatest charge of powder, does not move at a greater rate than 2400 feet per second, or little more than 27 miles per minute. The velocity of the ball again is promoted by the sudden propagation of the heat through the whole body of the air, as soon as it is extricated from the materials of which the gunpowder is made, so that it is enabled to strike all at once, and thus greatly to augment the movements of the ball. We may conclude, upon these principles, that the force of an explosion depends, first, on the quantity of elastic fluid to be expended; second, on the velocity it acquires by a certain degree of heat; and, third, on the celerity with which the degree of heat affects the whole of the expansile fluid. These three take place in the greatest perfection where the electric fluid is concerned, as in lightning, earthquakes, and volcanoes. (See STEAM).

EXPONENT, in *mathematics*, is the index of a root or power. For instance, if a quantity is multiplied by itself any number of times, instead of repeating the factor so many times, we place over it, on the right, a figure denoting how often the number or magnitude has been multiplied by itself; e. g. $a^4 = aaaa = a, a, a, a$, $9^3 = 9 \times 9 \times 9 = 729$.

EXTENSION, in *philosophy;* one of the common and essential properties of body, or that by which it possesses or takes up some part of universal space.

EXTINGUISHER. The instrument commonly employed for extinguishing the light of a candle may have its value very materially increased, and indeed may be made self-acting, by a very small addition to its cost. The arrangement is shown in the accompanying engraving. It is placed on the candle and firmly fastened with a *clip*, held together by a small ring, and a wire or needle thrust into the tallow is made to support the extinguisher. As soon as the candle burns sufficiently low to permit the escape of the pin, the extinguisher falls, and, by entirely closing every passage for the admission of air, extinguishes the light.



EXTRACT (*extractum*). When chemists use this term, they generally mean the product of an aqueous decoction. In pharmacy, it includes all those preparations from vegetables which are separated by the agency of various liquids, and afterwards obtained from such solutions, in a solid state, by evaporation of the menstruum. It also includes those substances which are held in solution by the natural juices of fresh plants, as well as those to which some menstruum is added at the time of preparation. Now, such soluble matters are various, and mostly complicated, so that chemical accuracy is not to be looked for in the application of the term. Some chemists, however, have affixed this name to one particular modification of vegetable matter, which has been called *extractive*, or *extract*, or *extractive principle;* and, as this forms one constituent part of common extracts, and possesses certain characters, it will be proper to mention such of them as may influence its pharmaceutical relations. The extractive principle has a strong taste, differing in different plants: it is soluble in water, and its solution speedily runs into a state of putrefaction, by which it is destroyed. Repeated evaporations and solutions render it at last insoluble, in consequence of its combination with oxygen from the atmosphere. It is soluble in alcohol, but insoluble in ether. It unites with alumine, and, if boiled with neutral salts thereof, precipitates them. It precipitates with strong acids, and with the oxides from solutions of most metallic salts, especially the muriate of tin. It readily unites with alkalies, and forms compounds with them, which are soluble in water. No part, however, of this subject, has been hitherto sufficiently examined. In the preparation of all the extracts, the London Pharmacopœia requires that the water be evaporated, as speedily as possible, in a broad, shallow dish, by means of a water-bath, until they have acquired a consistence proper for making

pills; and, towards the end of the inspissation, that they should be constantly stirred with a wooden rod.

These general rules require minute and accurate attention, more particularly in the immediate evaporation of the solution, whether prepared by expression or decoction, in the manner, as well as the degree, of heat by which it is performed, and the promotion of it by changing the surface by constant stirring, when the liquor begins to thicken, and even by directing a strong current of air over its surface, if it can conveniently be done. It is impossible to regulate the temperature if a naked fire be used; and, to prevent the extract from burning, the use of a water-bath is, therefore, absolutely necessary.

Extractor, in *midwifery;* an instrument, or forceps, for extricating children by the head.

Extrados; the outline of an arch.

Extravasation, in contusions, and other accidents of the cranium, is when one or more of the blood-vessels distributed on the *dura mater* are broken, whereby there is such a discharge of blood as oppresses the brain, frequently bringing on violent pains, and at length death itself, unless the patient is timely relieved.

Extremities. This term is applied to the limbs, as distinguishing them from the other divisions of the animal, the head and trunk. The extremities are four in number, divided, in man, into upper and lower; in other animals, into anterior and posterior. Each extremity is divided into four parts; the upper into the shoulder, the arm, the fore-arm, and the hand; the lower into the hip, the thigh, the leg, and the foot.

Eye. Of all our coporeal senses that of vision may be considered as the most obviously essential to the acquirement of knowledge.

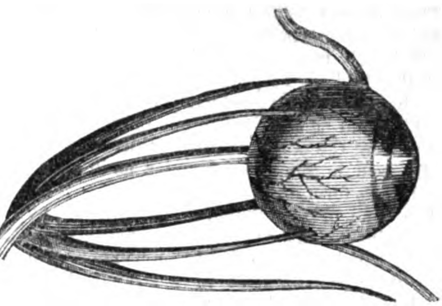
The eye, though the most wonderful, and at the first view the most complicated part of animal anatomy, is in reality nothing more than a camera-obscura; the various humours forming one powerful lens of an exceeding short focal distance on one side, while, on the other, it is allowed to embrace a very considerable space, and this is called the field of vision.

In order that we may properly understand the nature of vision, it will be necessary to furnish a brief anatomical description of the eye; which is composed of several coats or cases, one within the other, and filled with transparent humours of different degrees of density. The outer coat of the eye is called the sclerotica. It is exceedingly strong, and the muscles that move the eye are attached to it. What is called the white of the eye is a part of this coat. The cornea bulges out a little from the eyeball; it is circular, and exceedingly transparent. The next coat to the sclerotica is called the choroides, which serves as a lining to it. It is of a dark colour in the human eye, but white in cats and owls, and green in most animals that live on grass and vegetables. Its texture is soft and pulpy, and too weak to be susceptible of muscular motion, except at its extremities towards the front of the eye. Like the sclerotica, it is distinguished into two parts; the fore part being called the iris, while the hinder part retains the name of the choroides. The iris commences immediately under the commencement of the cornea. It there attaches itself more strongly to the sclerotica by a cellular substance, forming a kind of white, narrow, circular rim, called the ciliary circle. The iris is that remarkable circle which gives the eye its character as to colour; it is composed of two sets of muscular fibres; the one tending, like radii, towards the centre of the circle, and the other forming a number of concentric circles round the same centre. The central part of the iris is perforated, and the aperture, which is called the pupil, is always round, but varied in diameter by the action of the two sets of muscular fibres composing the iris. When a very luminous object is viewed, the circular fibres contract, the radial are relaxed, and thus the size of the pupil is diminished; on the other hand, when the objects are dark and obscure, the radial fibres of the iris contract, the circular are relaxed, and the pupil is enlarged, so that it admits a greater quantity of light. By candle-light, the contraction and dilation of the pupil may be very distinctly observed, with the assistance of a looking-glass. If, with our eyes directed to the mirror, we bring the candle close to our face, we shall find the pupil become very small; if the candle be removed, and completely shaded for about a minute, and then brought to its former place, it will be found that the pupil has greatly dilated, and that it again contracts as the light draws nearer: if the light shine much more strongly on one eye than the other, the pupil of the shaded eye will not contract so much as the other. The whole of the choroide membrane is opaque, by which means no light can enter the eye but what passes through the pupil: but to render the chamber of the eye still darker, the posterior surface of this membrane is covered with a dark-coloured mucus, called the pigmentum. Under the iris, there is a prolongation of the choroides, which forms a circular band of radial fibres, turning inwards towards the centre of the eye, and filled up between with a black mucus, giving it the appearance of a membrane. This circular band is called the ligamentum ciliare, or ciliary ligament. The third and *last* coat of the eye is called the retina. This is a fine and delicate membrane, being an expansion of the optic nerve, which proceeds from the brain. It is spread, like a net of exquisite delicacy, all over the concave surface of the choroides, and terminates at the ciliary ligament. It receives the images of objects, which are depicted upon it by the rays of light that enter at the pupil. It is of itself transparent, and of an ash-coloured white, but appears black on account of the dark-coloured pigmentum behind it. The optic nerve, which passes through a small hole in the bony cavity containing the eye, and conveys to the sensorium the impressions made on the retina, is not in the centre of the eye, but a little on one side, inclining towards the nose.

The tunica choroides is described by some authors as consisting of two laminæ. This description, however applies much more accurately to the eyes of some animals, particularly to those of sheep, than to those of man. Those who suppose the choroides to consist of two laminæ, describe the external one as terminating at the ciliary ligament, and the internal one as extending farther, to form the iris. The iris is described as consisting of two laminæ, and it is very certain that two sets of fibres may be observed. These are supposed to be muscular, and from the mobility of the iris, there seems no reason to doubt of their being really so. Some of the fibres are orbiculor, and lie round the pupil; others are straight, and extend from the circumference of the iris to its centre. We have seen that the iris has motions of such a

nature, that the pupil is contracted on the approach of a strong light and is dilated in proportion as the light is less vivid. By this admirable yet simple contrivance, the eye adapts itself to the different proportions of light to which it is exposed. If the iris was always as much contracted as it is when exposed to the light of noon-day, a weaker light, such as that of the moon, could not be admitted in sufficient quantity to answer any useful purpose. On the contrary, if the pupil was immovably dilated, we might take advantage of the scattered rays of light, but should be distressed and blinded by the bright effulgence of the mid-day sun. When a strong light succeeds to darkness, we are under the necessity of closing the eyelids, or of turning away the head, till the pupil has been accommodated to the change by the contractile powers of the iris. Cats, and some other animals which prey after night-fall, have the greatest power of changing the size of the pupil, though it is an erroneous opinion to suppose that they can see in the dark. Nearly the whole of the curtain of the eye can be drawn back to accommodate itself to a very dilule ray, but without light they cannot see.

The three transparent substances inclosed by the coats of the eye, are called the aqueous, crystalline, and vitreous humours. They are shown in the section *Plate* Ear and Eye, *fig*. 4. The first of these, or *aqueous* humour, resembles water, whence its name. It gives a protuberant figure to the cornea, filling the two cavities between the cornea and ciliary ligament, which cavities communicate by the pupil. The refractive power of the aqueous humour is similar to that of water.—The second, or *crystalline* humour, is, like the former, transparent, in which it exceeds that of the purest crystal; it has the consistence of a hard jelly, growing somewhat softer from the middle towards the edges. Its form is that of a double convex lens, but more convex on the interior than the exterior surface.—Resembling a lens in its form, it also resembles one in its use: it converges the rays which pass through it from every visible object to its focus on the retina. It is inclosed in a fine transparent cover, or membrane, which is attached to the ligamentum ciliare, and by that means it is suspended. The radial fibres of the ligamentum ciliare have the power of contracting and dilating occasionally, by which means they alter the shape or convexity of this natural lens, and shift it a little backward or forward in the eye, so as to adapt its focal distance from the retina to the different distances of objects. Without this, or some equivalent arrangement, we should only see those objects distinctly that were at one distance from the eye.—At the back of the crystalline lies the third, or vitreous humour. The *vitreous* humour was so called from a supposed resemblance to melted glass; it is a clear and gelatinous fluid, very much resembling the white of an egg. It fills about three-fourths of the globe of the eye, and extends from the posterior part of the eye as far as the ciliary ligament. It is contained in a fine transparent capsule, or membrane, and when carefully removed from the globe of the eye, preserves its consistence for some time, being supported by its capsule, but afterwards runs off, and the capsule diminishes in size. The thin capsule which surrounds the vitreous humour sends off a number of membranous processes into the vitreous substance, where they form cells, which communicate with each other, and afford a high degree of firmness and tenacity to the whole mass. The eye, with its muscles, and nerve is shown beneath.



Dr. Brewster has very accurately ascertained the amount of refraction in the various coats and humours of the human eye, as well as the relative measures of those bodies; and as the results differ from those of Dr. Wollaston and others, who had previously examined the subject, they may be considered of considerable importance in the anatomy as well as the optical properties of that organ. Taking the refractive power of water at 1.3358, the following table will convey the result of Dr. Brewster's experiments.

Refractive power of the	aqueous humour	1.3366
	vitreous humour	1.3394
	outer coat of crystalline	1.3767
	middle coat of ditto	1.3786
	central part of ditto	1.3990
	whole crystalline	1.3839

		Inch.
Diameter of the	crystalline	0.378
	cornea	0.400
Thickness of the	crystalline	0.172
	cornea	0.042

The direct action of light on the retina may easily be illustrated. If we suppose a pencil of rays radiating from a luminous surface, those which impinge on the opaque sclerotica are reflected, and have no concern in the production of vision, while those which by falling very obliquely, form a very considerable angle with the cornea, are also reflected without penetrating into the aqueous humour. The rays, which fall within an angle of about 48 degrees, pass through this membrane, undergoing a certain refraction, by which they are brought nearer to the line of the axis of the cornea; and, if produced, would converge into a focal point beyond the bottom of the eye. From the cornea, the rays pass into the aqueous humour.—They are there divided by the dispersive powers of this fluid, so that, if continued in the same medium, they would not only converge beyond the back of the eye, but, on account of the aberration caused by their different refrangibility, would produce a confused and coloured image.

The rays collected by the cornea pass through the pupil. Those which come in an unfavourable direction are either reflected by the iris, or absorbed by the pigmentum on its posterior surface. The pupil admits only those rays which are nearest to the axis of vision. They then meet with the crystalline, which, by its refractive power, collects them, and brings them into foci, after passing through the less refrac-

tive medium of the vitreous humour on the concave surface of the retina. See *Plate* EAR and EYE, *fig*. 5.

They do not impart a correct perception of the body which reflects them, unless they fall on the retina precisely in the order in which they are detached from that body. To produce this effect, it is necessary that all the rays which proceed from any one point, should be collected in one point of the retina; and that all the points of union thus formed, should be disposed in the same manner as in the body, of which they form an image.

The cone of rays which proceeds from any luminous point to the cornea forms another cone, the apex of which falls on the retina. These two cones have their axes almost in a straight line. That which is perpendicular to the middle of the crystalline proceeds directly to the bottom of the eye; that which comes from above falls inferiorly; that on the left proceeds to the right, and so on with respect to the others; thus an inverted image is formed on the retina.

There are five natural methods by which we judge of the distance of objects from the eye. First, by the angle which is made by the optic axes; for want of this direction, it has been observed, that persons who are blind of one eye, frequently make a slight mistake as to the situation of objects. Secondly, by the apparent magnitude of the objects. By depending upon this method, we are frequently deceived in our estimates of distance by any extraordinary large objects; as in approaching a large city, or edifice, we fancy them nearer than they really are. This furnishes us with a reason why animals and other small objects seen contiguous to large mountains appear exceedingly small; for we imagine the mountain to be nearer to us than it actually is. When we look down also from a high building, the objects beneath us appear much smaller than they would at the same distance on the level ground; the reason is, plainly, because we have no distinct idea of distance in that direction, and therefore judge by the impressions upon the retina, whereas custom has corrected our judgment in the other case. The third method of determining the distance of objects is by the force and vividness of the colours; and the fourth is analogous to it; namely, by the different appearance of the minute parts. When these appear distinct, we judge the object to be near; and the contrary, when they appear faint and confused. Fifthly, we are assisted in judging of the distance of any particular object by the other objects which are interposed. On this account distances upon uneven ground do not appear so great as upon plain; for the valleys, rivers, and other objects that lie low, are many of them lost to the sight. This, too, is the reason why the banks of a river appear contiguous when the river lies low and is not seen.

Though every object that is before our eyes has its image in both organs, yet objects are not seen double; because, having previously ascertained, by help of the touch, that such an object was single, at the same time that each optic axis was directed towards it, and its image was painted in the corresponding parts of each retina, we have connected the idea of unity with the sentiment of those impressions, and have accustomed ourselves to identify two sensations, which, so to speak, are in unison with one another. But if the two optic axes no longer concur towards the same point, as when we slightly press one eye sideways with the hand, the object appears double, and it is evident that the two images do not then fall on the corresponding parts of the retina.

It has often been a subject of inquiry, why we see objects in their true position, though the image on the retina is inverted, but no satisfactory solution of the difficulty has ever been given. And we should be as little likely to receive an answer, if we were to ask, why we do not preceive every object bent, because the image of it is depicted upon a concave surface. It is certain, that unless distinct images are painted on the retina, objects cannot be clearly perceived. If, from too little light, remoteness, or any other cause, a picture is indistinctly painted on the retina, an obscure or indistinct idea of the object is conveyed to the mind. The picture on the retina is, therefore, so far the cause of vision, that our ideas of visible objects vary as it varies, and when it is not formed, nothing is seen. Yet we may fairly conclude that the mind does not look upon the image on the retina; for in cases of the gutta serena, a disorder which affects only the optic nerve, the pictures on the retina are as perfectly formed as in the best eyes, although the patient is afflicted with incurable blindness. It is the optic nerve, therefore, which conveys the impressions made on the retina to the brain; but how they are communicated to the mind, is screened from the view of man. It has been supposed that we acquire by experience the habit of seeing objects erect; but there are many striking facts to prove the contrary: persons who have been blind from infancy, and who have been suddenly restored to sight by a surgical operation, have not been led into the smallest mistake. In fact, no reason can be given why the mind should not perceive as accurately the position of bodies, when the rays reflected from the upper part of those bodies fall upon the lower parts of the eye, as if the contrary took place.

The impressions of light on the retina appear to be always in a certain degree permanent, and the more so as the light is stronger; but it is uncertain whether the retina possesses this property merely as a phosphorescent body, or in consequence of its peculiar organization. The duration of the impression is usually limited to less than half a second: hence, a luminous object revolving in a circle, makes a lucid ring: and a shooting star leaves a train of light behind it, which is not always real. If the object is painfully bright, it generally produces a permanent spot, which continues to pass through various changes of colour for some time, and then gradually vanishes. Dr. Roget, in an ingenious paper published in the Transactions of the Royal Society, has farther illustrated this subject by reference to the revolution of a wheel made to revolve behind a series of perpendicular bars, which change in appearance from radical spokes to curved lines. This effect may, however, be better illustrated by reference to *fig*. 6, *Plate* EAR and EYE.

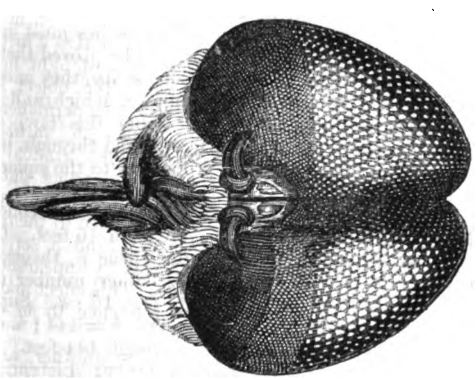
It may now be advisable to examine another, and no less important part of the anatomy of this organ, or the arrangement made for its protection from any inconvenience that may arise from the attacks of insects, or the particles of dust which are continually floating in the air. This is effected by the *eyelids*, which, like two substantial curtains, protect and cover the eyes when we are asleep; and, while waking, they diffuse, by their motion, and by peculiar secret-

ing organs, a fluid over the eye, which cleans and polishes it.

The *eyebrows* also defend the eye from the rays of light which might otherwise prove too strong for the optic nerve; and that the *eyelid* may shut with greater exactness, each edge is stiffened by a cartilaginous arch, from which proceed the eyelashes, thus serving to warn the eye of dangers, while it protects it from the straggling mote.

The more we investigate the works of nature, the greater reason have we to admire the wisdom of its Author; and that wonderful adaptation of our organs, in the minutest particulars, to the general laws which pervade the universe. The mechansim of the eye affords a striking illustration of this remark. We have hitherto supposed the eye to be a lens possessing the power only of enlarging and contracting its dimensions; and from the previous description given of the rays of light, it may be considered as incapable of obviating the confusion which must arise from their different degrees of refrangibility. But here the use of that wonderful structure of parts, and the different fluids in the eye, is clearly seen. The eye is, in fact, a compound lens; each fluid has its proper refrangible power. The shape of the lenses is altered at will, according to the distance of the object; and the three substances having the proper powers of refrangibility, the effects of an achromatic glass are without difficulty produced by the eye.

The eyes of fish differ very much in form from those we have been now describing. The crystalline lens is round, instead of being flattened, as in the human eye. This arrangement is necessary from the circumstance that they view all objects through a much denser medium, and as such they require a greater magnifying power. But one of the most extraordinary exceptions to the ordinary laws of nature in this respect, will be found in the common house fly, of which an example is given beneath. Hundreds of eyes, or distinct organs for the purposes of vision, are here congregated together, and the little insect is thus enabled to see distinctly any approaching danger, without moving its body.



FAÇADE is the outside or external aspect of an edifice. As in most edifices only one side is conspicuous, viz., that which faces the street, and usually contains the principal entrance, this has been denominated, *par eminence* the *façade*. As a work of architecture, it must form a whole, of which all the parts are properly related and symmetrically arranged, and correspondent to the character or style of the edifice.

FACE; the front part of the head, the seat of most of the senses, is composed of the forehead, the eyelids and eyebrows, the eyes, the nose, the cheeks, the mouth, the lips, the jaws, the teeth. Beneath the skin, which, in the face, is more delicate, more soft, more sensitive and clear than in other parts, are numerous muscles, by which the motions of the skin are produced. They are enveloped in fat. There are, also, a greater number of vessels and nerves in the face than in any other external part. Underneath these is the bony basis, which, exclusive of the teeth, is composed of 14 bones, called, in anatomy, the *bones of the face*. The anterior part of the skull (*os frontis*) also forms an important feature of the face. Of all these bones, the lower jaw, only, is movable, being articulated with the basis of the skull. The other bones are firmly joined together, and incapable of motion. The character of each individual is strongly marked by the conformation of the countenance. (See PHYSIOGNOMY.) The face also acquires its expression from bodily habits and actions, and particularly from diseases. The form of the bones produces a great difference in the external appearance of the face, in brutes and in men. The jaws of the former are more projecting, so as to form an acute angle with the forehead; those of the latter recede in proportion to the prevalence of the human formation and beauty. On this relation of the jaw to the forehead is founded the facial line described under CRANIUM.

FACIAL ARTERY, in *anatomy*, is synonymous with the external maxillary.

FACING, in *ship carpentry*, is letting one piece of timber into another with a rabbet.

FAC SIMILE; an imitation of an original in all its traits and peculiarities; a copy as accurate as possible. Thus fac similes of old manuscripts, or of the handwriting of famous men, or of interesting documents, are made in engraving or lithographic prints. The object of fac similies is various; in the case of old manuscripts, they are intended to show the age of the MS. by the nature of the characters.

FACTOR, in *arithmetic*, is any number which is multiplied by another: thus 7 and 4 are the factors of 28. They are divided into simple and composite. A simple factor is one which is divisible only by itself.

In commerce a *factor* is an agent, employed by merchants residing in other places, to buy and sell, and to negociate bills of exchange, or to transact other business on their account. Establishments for trade, in foreign parts of the world, are called *factories*.

FADEN; a German measure corresponding to the *fathom*, equal to a *klafter*, or six feet.

FAÏENCE, imitation porcelain; a kind of fine pottery, superior to the common pottery in its glazing, beauty of form, and richness of painting. It derived its name from the town of Faënza, in Romagna, where it is said to have been invented in 1299. A fine sort of pottery was manufactured there at that period, which the Italians called *Maiolica*, probably from its inventor. Some pieces were painted by the great artists of the period, Raphael, Giulio Romano, Titian, and others, which are highly valued, as monuments of early art. The *Maiolica* reached its highest perfection between 1530 and 1560. The King of Würtemberg possesses a rich collection of it.

The modern Faïence appears to have been invented, about the middle of the 16th century, at Faënza, and obtained its name in France, where a man from Faënza, having discovered a similar kind of clay at at Nevers, had introduced the manufacture of it. Towards the end of the 17th century, the city of Delft, in Holland, became famous for the manufacture of Faïence, which was called also *Delft-ware*. It does not, however, resist fire well. Our own stone ware, made of powdered flint, has some external resemblance to the Faïence, but is, in reality, entirely different.

Fair, in *commerce;* a greater kind of market granted to a town, by privilege, for the more speedy and commodious buying and selling, or providing such things as the place stands in need of. These fairs are usually held twice a year; in some places only once a year; and, by statute, they shall not be held longer than they ought by the lords thereof, on pain of their being seized into the king's hands, &c. Also proclamation is to be made, how long they are to continue; and no person shall sell any goods after the fair is ended, on forfeiture of double the value, one fourth to the prosecutor, and the rest to the king. There is a toll usually paid at fairs, for the privilege of erecting stalls, from which to sell goods, as well as booths, either for entertainment or pastime.

The most important fairs now held are, probably, those of Germany, and particularly the Leipsic fairs. In German, a fair is called *Messe*, which also signifies a mass. High masses, on particular festivals, collected great numbers of people, and thus, probably, became the origin of markets, and, at a later period, of fairs, which, as we have already said, are only privileged markets. The three chief fairs of Germany are those of Leipsic, Frankfort on the Maine, and Brunswick. The Leipsic book-fair is unique. The Leipsic fair, beginning January 1, is called *New-year's fair:* the Easter fair, or Jubilee fair, begins on Jubilee Sunday, and Saint Michael's fair, on the Sunday after September 29. Each lasts three weeks, but only the two last are important. The Easter fair is the most important. Frankfort on the Maine has the Easter fair and Autumn fair, and Brunswick, the Candlemas fair and St. Lawrence's fair. Important fairs are also held at Alessandria and Sinigaglia in Italy, at Lyons and Beaucaire in France, Bolzano in the Tyrol, Zurzach in Switzerland, Niznei-Novgorod in Russia, Warsaw in Poland, &c. But fairs cannot now have the importance which they formerly had, because the communication between different parts of a country has become so easy that merchandise is much oftener ordered directly than formerly.

Fairy Circle, or Ring; a phenomenon frequent in the fields, &c., supposed by the vulgar in England to be traced by the fairies in their dances. There are two kinds: one of about seven yards in diameter, containing a round, bare path, a foot broad, with green grass in the middle of it. The other is smaller in size, encompassed with a circumference of grass, greener and fresher than that of the middle. Some attribute them to lightning, and others to a kind of fungus which breaks and pulverizes the soil.

Fake; one of the circles or windings of a cable or hawser, as it lies disposed in a coil. The fakes are greater or smaller, in proportion to the extent or space which a cable is allowed to occupy where it lies.

Fall of Bodies. All bodies on the earth, by virtue of the attraction of gravitation, tend to the centre of the earth. If this tendency acts freely, the body falls towards the earth; if it is opposed by some obstruction, pressure ensues; if the tendency is partly checked and partly efficient, pressure and descent both ensue. A ball, held in the hand, presses downward; if dropped, it descends perpendicularly; if placed on an inclined plane, it rolls down; in doing which it presses the plane with part of its weight. The laws, according to which this motion takes place, were formerly the subject of the most erroneous theories.

According to the physics of Aristotle, the velocity of the fall of bodies is in proportion to their weight. Consequently any body should fall with ten times more velocity than another, which is only one tenth part as heavy. This error Galileo attacked, while a student in Pisa. Soon after his appointment to a professorship, he declared himself against this and other maxims of the Peripatetic philosophy. He ascended the cupola of the lofty tower at that place, and dropped bodies of very unequal weight, which, if their specific gravity did not differ too much, were found to reach the ground at nearly the same time. Galileo eventually proved, when professor in Padua, the correctness of his position, by means of two pendulums, of equal length, and very unequal weight, which, nevertheless, performed their vibrations with equal velocity. Equally erroneous hypotheses have been grounded on the fact, that the velocity of the descent increases in proportion to the space passed through. The Aristotelians said, that all bodies had a natural tendency to the centre of the earth, and hastened towards it with more velocity the nearer they approached it. Others explained the accelerated rapidity of the descent by the augmented pressure of the atmosphere; and the general opinion was that the velocity increased in the same proportion as the space passed through, and, consequently, that a body, after falling five fathoms, would have five times the velocity it had after falling through one fathom—an opinion, which, notwithstanding its great simplicity and plausibility, involves an absolute impossibility. Galileo, at length, arrived at the true opinion, that the velocity of falling bodies must increase in proportion to the time; and he proved that, as bodies can never be destitute of gravity, they must every instant receive a new impulse, which unites with the effect of the former. From this law, it moreover follows, that the spaces passed through, by bodies falling freely, are in proportion to the square of the times.

Experiments have shown that, in the first second, the fall amounts to a little more than 16 feet. In order to ascertain, therefore, the space h, through which a body would fall in any other number of seconds t, we have the equation $1 : t^2 :: 16 : h$. Supposing, for example, $t = 3$, we have $h = 144$; i. e. in three seconds, the body falls through 144 feet.

Fallopian Tubes, in *anatomy*, are two ducts arising in the womb, one on each side of the fundus, and thence extended to the ovaries. These are called *tubes*, from their resemblance to a trumpet, and *Fallopian* from Gabriel Fallopius, a physician of Italy, in the 16th century, who is reported to have first ascertained their use and office.

Fallow Land is ground that has been left untilled for a time in order that it may recover itself from

an exhausted state; but to render a barren soil fertile, it ought to be frequently turned up to the air, and to have mixed with it manures of animal dungs, decayed vegetables, lime, marl, sweepings of streets, &c. In turning over the soil, the chief implements of the gardener are the spade, the hoe, and the mattock; and those of the farmer are the plough, the harrow, the roller, the scythe, and the sickle. As a succession of the same crops tends to impoverish the soil, a rotation of different crops is necessary. Potatoes, grain, and white crops are exhausting; but, after them, the soil is ameliorated by tares, turnips, and green or plant crops.

False, in *music;* an epithet applied by theorists to certain chords, called *false*, because they do not contain all the intervals appertaining to those chords in their perfect state: as a fifth, consisting of only six semitonic degrees, is denominated a *false* fifth. Those intonations of the voice which do not truly express the intended intervals are also called *false*, as well as all ill-adjusted combinations; and those strings, pipes, and other sonorous bodies which, from the ill disposition of their parts, cannot be accurately tuned. Certain *closes* are likewise termed *false*, in contradistinction to the full or final close.

Falsetto; that species of voice in a man, the compass of which lies above his natural voice, and is produced by artificial constraint.

Fanfare; a short, lively, loud, and warlike piece of music, composed for trumpets and kettle-drums. Also small, lively pieces, performed on hunting horns, in the chase. From its first meaning is derived *fanfaron*, a boaster, and *fanfaronade*, boasting.

Fantasia; the name generally given to a species of composition supposed to be struck off in the heat of imagination and in which the composer is allowed to give free range to his ideas, and to disregard those restrictions by which other productions are confined. Some writers limit the application of this term to certain extemporaneous flights of fancy; and say, that the moment they are written, or repeated, they cease to be *fantasias*. This, they add, forms the only distinction between the *fantasia* and the *capricio*. The *capricio*, though wild, is the result of premeditation, committed to paper, and becomes permanent; but the *fantasia* is an impromptu, transitive and evanescent, exists but while it is executing, and, when finished, is no more.

Farina; the most important part of vegetable food. A patent has lately been obtained for procuring nutritious food of this description, which is exceedingly economical.

The patentee proposes to prepare from carrots, turnips, beetroot, mangelwurzle, or potatoes, or any other roots of that kind which may be conveniently obtained, a fine white and nutritious farinaceous substance, capable of being converted to the best white bread, and to all the purposes of fine wheaten flour; and also into sugar.

The roots are to be washed perfectly clean, or deprived of their skins, and are to be cut into thin slices, and then submitted to the action of a solution of acid in water; sulphuric acid is to be preferred, but any of the other acids will answer the purpose. The quantity of acid to be employed will depend upon the roots to be acted upon: from two to ten pounds of acid will be required for every hundred weight of roots; carrots will require the smallest quantity of acid, potatoes the greatest.

This steeping of the roots in the solution of acid, will perfectly change their characters and taste, and when they are sufficiently acted upon, the acid and other matters held in solution, are to be removed from the slices of the roots, by washing them repeatedly with pure water. They may be afterwards dried by exposure to the air and sun, or by a kiln at a low temperature; and when the mixture has been evaporated, and the slices of the roots brought to perfect dryness, they may be submitted to the operation of a mill, and ground into farina or white flour in the ordinary way.

The slices of roots thus prepared will retain their nutritious properties unimpaired for any length of time, and in any climate, if not exposed to damp; and the flour obtained from grinding them will have exactly the same properties, appearance, and flavour, as wheaten flour.

In preparing sugar from the said roots, they are to be washed and sliced, and submitted to the action of the acid in the way above described, and then reduced into farina, as a first part of the process. The farina is then to be boiled with a solution of acid, in the proportion of about two pounds of the acid to one hundred weight of the farina. A saccharine matter is produced by this operation, which may be crystallized or granulated into sugar, by the ordinary mode of evaporating cane juice, or other vegetable extracts from which sugar is commonly made.

Instead of reducing the roots to a farinaceous powder, as last described, for the production of sugar, they may be steeped in their raw state in a solution of acid, in the proportion of ten pounds of acid to every hundred weight of roots; and after having been acted upon by the acid for about three days, the saccharine matter will be produced, which may be treated as before described, and sugar obtained therefrom.

Farthing; the fourth part of a penny; originally the *fourth thing*, or the fourth in the integer one penny.

Fascets, in *glass making;* the irons thrust into the mouths of the bottles when employed to remove them into the annealing oven.

Fascines; bundles of boughs, twigs, &c., sixteen feet in length, and usually one foot in diameter. They are made on trestles, or any kind of support placed about two feet asunder. The twigs are placed on this machine, drawn tightly together by a cord; the bands are then passed round them at the distance of two feet from each other. The twigs which exceed a given length are cut off or bent back, and the ends are bound into the bundle. Fascines are used in sieges, hydraulic constructions, &c. Very long, thin ones are used in constructing batteries, whence they are called *saucissons*, or *battery-sausages*.

Fashion Pieces; the aftmost or hindmost timbers of a ship, which terminate the breadth, and form the shape of the stern. They are united to the stern post, and to the extremity of the wing transom by a rabbet, and a number of strong nails or spikes driven from without.

Fat of Animals. Animal oils and fats, as they differ only in the fluidity of the former at common temperatures, while the latter are generally concrete, will be treated of together in the present article. Of animal oils, whale oil and sperm oil are most generally known in this country; and among the princi-

pal varieties of fat are, spermaceti, butter, tallow, lard, and suet. Whale oil, or train oil, is extracted from the blubber of the whale (principally the *balæna mysticetus*). Originally it is a firm, solid fat. To obtain the oil, the blubber is melted in large copper vessels. A large quantity of water separates, and on the surface there floats a solid matter, called *fenks*, which is probably coagulated albumen. The more moderate the heat, and the shorter its duration, the paler and better is the oil; but this is attended with a diminution in its quantity. The deep colour is owing partly to too great heat in the boiling, and partly to blood and other impurities, which are unavoidably mixed with it. What is carefully extracted in Greenland is perfectly pale and limpid, and free from smell, and burns with a pure and bright flame.

Whale oil requires to be kept in close vessels, to prevent the action of the air. It is rendered more fluid and combustible by adding to it a little cold-drawn linseed oil; but it cannot, by any treatment, be made so fit for burning in lamps as spermaceti oil. The best way of using it is found to be by converting it into gas. It may be deprived of its offensive odour, however, by the use of chloride of lime. Its specific gravity is 0.9191. It boils at 640° Fahr., and may be distilled; but its properties are then materially altered, or, rather, it becomes a new substance, its specific gravity being diminished to 0.868, its boiling point lowered, and its inflammability much increased. Whale oil consists of carbon 68.87, oxygen 16.10, and hydrogen 15.03.

Sperm oil, or spermaceti oil, forms part of the oily substance found in the cranium of the spermaceti whale, or *physeter macrocephalus*. The oil is separated by putting the mass into a woollen bag and pressing it, by which the fluid is made to run out, and the solid residue, when washed with a weak alkaline ley, affords spermaceti. This kind of oil is much purer than train oil, and burns away without leaving any charcoal on the wicks of lamps. In composition it differs but slightly from whale oil, consisting, according to Doctor Ure, of carbon 78, oxygen 10.20, and hydrogen 11.80. The fat of animals, or more solid animal oils, may be separated from the membranous and other substances with which it is united by melting it at a gentle heat, with the addition of a small quantity of water. Fat thus prepared is called *lard*, when of a soft consistence, and *tallow* when harder. It is insipid, and sometimes free from smell; at others, it has a distinct and peculiar odour. It is apt to become rancid, however, by keeping—a change connected with the absorption of oxygen. It is insoluble in water or in alcohol. It melts at 90° or 100° Fahr.; by raising the heat it is rendered more acrid, and exhales a pungent vapour. In close vessels it is decomposed, and, among other products, yields a large quantity of olefiant gas. It is inflammable, and affords, by combustion, water and carbonic acid.

The acids act chemically on fat. Sulphuric acid chars it. Nitric acid, mixed with it in a small quantity, gives it a firmer consistence, and renders it soluble in alcohol. In this state it has been called *oxygenated* fat. The animal oils and fats combine with the alkalies, and form with these perfect soaps. With some of the earths, and metallic oxides also, they form saponaceous compounds. They even facilitate the oxidation of some of the metals, as copper and mercury, by the atmospheric air. Animal fat is not homogenous, but consists of two different proximate principles, called *stearine* and *elaine*; the former of a firm consistence, resembling suet or tallow, the other more soft or liquid, and analogous to vegetable oils. (For an account of the mode of separating these principles, and their properties when separate, see STEARINE; and for a view of the theory of saponification, see SOAP.)

FATA MORGANA: a singular aërial phenomenon seen in the straits of Messina. When the rising sun shines from that point whence its incident ray forms an angle of about 45° on the sea of Reggio, and the bright surface of the water in the bay is not disturbed either by the wind or current, when the tide is at its height, and the waters are pressed up by currents to a great elevation in the middle of the channel, the spectator being placed on an eminence, with his back to the sun and his face to the sea, the mountains of Messina rising like a wall behind it, and forming the back ground of the picture—on a sudden there appear in the water, as in a catoptric theatre, various multiplied objects—numberless series of pilasters, arches, castles, well-delineated, regular columns, lofty towers, superb palaces, with balcônies and windows, extended alleys of trees, delightful plains, with herds and flocks, armies of men on foot, on horseback, and many other things in their natural colours and proper actions, passing rapidly in succession along the surface of the sea, during the whole of the short period of time while the above-mentioned causes remain.

All these objects, which are exhibited in the Fata Morgana, are proved by the accurate observations of the coast and town of Reggio, by P. Minasi, to be derived from objects on shore. If, in addition to the circumstances we before described, the atmosphere be highly impregnated with vapour, and dense exhalations, not previously dispersed by the action of the wind and waves, or rarified by the sun, it then happens, that, in this vapour, as in a curtain extended along the channel to the height of above forty palms, and nearly down to the sea, the observer will behold the scene of the same objects not only reflected from the surface of the sea, but likewise in the air, though not so distinctly or well defined as the former objects from the sea. Lastly, if the air be slightly hazy and opaque, and at the same time dewy, and adapted to form the iris, then the above-mentioned objects will appear only at the surface of the sea, as in the first case; but all vividly coloured or fringed with red, green, blue, and other prismatic colours. As the day advances, the fairy scene gradually disappears.

A very singular instance of atmospherical refraction is described in the *Philosophical Transactions*, as having taken place at Hastings. The coast of Picardy, which is between 40 and 50 miles distance from that of Sussex, appeared suddenly close to the English shore. The sailors and fishermen crowded down to the beach, scarcely believing their own eyes; but at length they began to recognise several of the French cliffs, and pointed out places they had been accustomed to visit. From the summit of the eastern cliff or hill, a most beautiful scene presented itself: at one glance the spectators could see Dungeness, Dover cliffs, and the French coast, all along from Calais to St. Vallery; and, as some affirmed, as far to the westward even as Dieppe. By the telescope, the French fishing-boats were plainly seen at anchor, and the different colours of the land on the heights

with the buildings, were perfectly discernible. This refractive power of the atmosphere was probably produced by a diminution of the density of its lower stratum, in consequence of the increase of heat communicted to it by the rays of the sun, powerfully reflected from the surface of the earth. (See MIRAGE.) Similar appearances occur also in the great sandy plains of Persia, of Asiatic Tartary, in Lower Egypt, on the plains of Mexico, in North America, &c.

FATHOM; a measure of six feet, used to regulate the length of the cables, rigging, &c., and to divide the lead (or sounding) lines, &c.

FAUX JOUR, or *false light*; an expression in the fine arts. If a picture is placed so that the light falls upon it from a different side from that from which the painter intended to represent the light in the picture as falling upon objects, or if the picture is placed so that it is covered with a bright glare, and nothing can be distinguished, the picture is said to be in *faux jour*.

FEEDER, in *canal-building*. In order that water may not be wanting in any part of a canal, built on different levels, a supply is insured at the highest level, and thus gradually passes off, through the locks, to the lowest. The streams, which furnish the water at this and other points, are called *feeders*.

FEELING; one of the five external senses, by which we obtain the ideas of solid, hard, soft, rough, hot, cold, wet, dry, and other tangible qualities. It is the most universal of all the senses. We see and hear with small portions of our bodies, but we feel with all. Nature has bestowed that general sensation wherever there are nerves, and they are every where, where there is life. Were it otherwise, the parts divested of it might be destroyed without our knowledge. It seems that, upon this account, nature has provided that this sensation should not require a particular organization. The structure of the nervous *papillæ* is not absolutely necessary to it. The lips of a fresh wound, the *periosteum*, and the tendons, when uncovered, are extremely sensible without them. These nervous extremities serve only to the perfection of feeling, and to diversify sensation.

Like every other sense, feeling is capable of the greatest improvement: thus we see that persons born without arms acquire the nicest feeling in their toes; and, in blind people, this sense becomes so much developed, that individuals born blind, and acquiring the faculty of sight in after-life, for a long time depend rather on their feeling than on their sight, because they receive clearer ideas through the former sense. A person in this condition, who could not remember the difference of things, if he only saw them, as soon as he touched them, distinguished them perfectly well. Feeling is the most common of all the senses, as it exists in all creatures, which have any sense at all: even some plants show a sensibility to touch. Many animals have no sense but that of feeling.

FELDSPAR. (See NATURAL HISTORY.)

FELLOE; the circular wooden rim, which, with the addition of a knave and spokes, makes the wheel of a carriage.

FELLOWSHIP; the name of a rule in arithmetic, useful in balancing accounts between traders, merchants, &c.; as also in the division of common land, prize-money, and other cases of a similar kind. Fellowship is of two kinds, single and double; or fellowship without time, and fellowship with time.

Single Fellowship is when all the moneys have been employed for the same time; and therefore the shares are directly as the stock of each partner. The rule in this case is as follows:—As the whole stock : the whole gain or loss : : each man's particular stock : his particular share of the gain or loss.—*Example*. A bankrupt is indebted to A 1000*l*. to B 2000*l*. to C 3000*l*.; whereas his whole effects sold but for 1200*l*.: required each man's share. Here the whole debt is 6000*l*.; therefore

$$\text{As } 6000 : 1200 : : \begin{cases} 1000 : 200l. \text{ A's share.} \\ 2000 : 400l. \text{ B's share.} \\ 3000 : 600l. \text{ C's share.} \end{cases}$$

Double Fellowship is when equal or different stocks are employed for different periods of time. The rule in this case is as follows:—Multiply each person's stock by the time it is engaged; then say, As the sum of the products : the whole gain or loss : : each particular product : the corresponding share of the gain or loss.—*Example*. A had in trade 50*l*. for 4 months, and B 60*l*. for 5 months, with which they gained 24*l*.: required each person's particular share.

$50 \times 4 = 200$
$60 \times 5 = 300$

$$500 : 24 : : \begin{cases} 200 : 9l.\ 12s. \text{ A's gain.} \\ 300 : 14l.\ 8s. \text{ B's gain.} \end{cases}$$

FELLING OF TIMBER, in *rural economy*. In the performance of this operation, attention should in the first place be paid to the season of the year, especially where the timber is of the oak kind or such as is to be peeled for the bark, as it will only peel, or what the workmen term *run*, at a particular period, which is generally in the spring months, just before the leaves expand. With many other sorts of timber trees, this is not, however, necessary to be regarded; but they should, in general, be cut down previously to the leaves appearing.

In the work of felling there is considerable art to make them fall in the best way, which is only known by those woodmen who have had much experience. Where a large fall is therefore to be made, it is of much advantage to have men of this kind to undertake the business. The price of felling is regulated by a variety of different circumstances, as the kind of wood, the size of the trees, the nature of the situation, &c; but the work is often done by the tree, or at a fixed price for a certain number of trees.

FELTING. The texture of modern hats, which are made of fur and wool, depends upon the process of felting, which is similar to that of fulling. The fibres of these substances are rough in one direction only, as may be perceived by passing a hair through the fingers in opposite directions. This roughness allows the fibres to glide among each other, so that when the mass is agitated, the anterior extremities slide forward in advance of the body, or posterior half of the hair, and serve to entangle and contract the whole mass together. The materials commonly used for hat-making, are the furs of the beaver, seal, rabbit, and other animals, and the wool of sheep. The furs of most animals are mixed with a longer kind of thin hair, which is obliged first to be pulled out, after which the fur is cut off with a knife.

The materials to be felted are intimately mixed together by the operation of bowing, which depends on the vibrations of an elastic string; the rapid alternations of its motion being peculiarly well adapted to remove all irregular knots and adhesions

among the fibres, and to dispose them in a very light and uniform arrangement. This texture, when pressed under cloths and leather, readily unites into a mass of some firmness. This mass is dipped into a liquor containing a little sulphuric acid; and, when intended to form a hat, it is first moulded into a large conical figure, and this is afterwards reduced in its dimensions by working it for several hours with the hands. It is then formed into a flat surface, with several concentric folds, which are still farther compacted in order to make the brim and the circular part of the crown, and forced on a block, which serves as a mould for the cylindrical part.

The nap, or outer portion of the fur, is raised with a fine wire brush, and the hat is subsequently dyed, and stiffened on the inside with glue. An attempt has been made, and at one time excited considerable expectation in England, to form woollen cloths by the process of felting, without spinning or weaving. Perfect imitations of various cloths were produced, but they were found deficient in the firmness and durability which belongs to woven fabrics.

Cloth has lately been made from the sweepings of the cotton factories by felting.

FELUCCA; a little vessel with oars, common in the Mediterranean.

FEMORALIS ARTERIA, in *anatomy;* a continuation of the external iliac along the thigh.

FEMUR, in *anatomy;* the thigh, or thigh-bone, a long cylindrical bone situated between the *pelvis* and *tibia.*

FENESTRA, in *anatomy;* a name given to two small holes which appear in the cavity of the tympanum, and which are distinguished from each other by the epithets *rotunda* and *ovalis.*

FENCE, in *agriculture;* a term signifying any sort of construction raised for the purpose of enclosing land, such as a bank of earth, a ditch, hedge, wall, railing, paling, or any similar kind of erection.

It seems evident that fences only became known, and were recurred to, as the pastoral state of society disappeared; and that during that of the feudal system they were but little necessary. The materials which are most commonly employed in the raising of fences are, earthy substances, living plants of various kinds, stones, bricks, and wood of different sorts. Irón, and even rope, or cord, are likewise occasionally made use of for forming fences.

FENNEL; a common plant, the seeds of which, by cultivation, acquire an agreeable flavour; they are carminative, and are frequently employed in medicine. In Italy, the young sprouts are eaten as a salad, and also in soups. Fennel seed is extensively exported from France to Great Britain, and is said to be employed in this country in the manufacture of gin.

FERMENTATION; the spontaneous changes which vegetable matter undergoes when exposed to ordinary atmospherical temperture. So long as vegetable substances remain in connection with the living plants by which they were produced, the tendency of their elements to form new combinations is controlled; but, as soon as the vital principle is extinct, they become subject to the unrestrained influence of chemical affinity. Owing to the difference in the constitution of different vegetable compounds, however, they are not all equally prone to fermentation; nor is the nature of the change the same in all of them. Thus alcohol, oxalic, acetic, and benzoic acids, may be kept indefinitely without alteration; while others, such as gluten, sugar, starch, and mucilaginous substances are very liable to decomposition. In like manner, the spontaneous change sometimes terminates in the formation of sugar; at another time, in that of alcohol; at a third, in that of acetic acid; and, at a fourth, in the total dissolution of the substance. This has led to the division of the fermentative processes into four distinct kinds, viz., the *saccharine,* the *vinous,* the *acetous,* and the *putrefactive* fermentation. When starch is kept moist for a considerable length of time, a change gradually ensues, and a quantity of sugar equal to about half the weight of starch employed is generated. Exposure to the atmosphere is not necessary to this change, though the quantity of sugar is increased by the access of air.

The conditions requisite for establishing the vinous fermentation are the following, viz., the presence of sugar, water, yeast, and a certain temperature. To observe the chemical changes which occur, we must dissolve five parts of sugar in about twenty of water, adding a little yeast, and, introducing the mixture into a glass flask, furnished with a bent tube, the extremity of which opens under an inverted jar full of water or mercury, apply a temperature of 60° or 70° Fahr., to the materials. In a short time, we shall observe the syrup to become muddy, and a multitude of air bubbles to form around the ferment; these unite, and, attaching themselves to particles of the yeast, rise along with it to the surface, forming a stratum of froth. The yeasty matter will then disengage itself from the air, fall to the bottom of the vessel, to acquire buoyancy a second time, and so on. The fermentation will continue for two or three days, when it will terminate, leaving the impurities to subside, and the liquor clear and transparent.

The only appreciable changes which are found to have occurred during the process, are the disappearance of the sugar, and the formation of alcohol (which remains in the flask), and of carbonic acid which is collected in the inverted jar. The yeast appears to have operated only by bringing on the fermentation, without farther contributing to the products. The atmospheric air, having been excluded by the nature of the apparatus, can have exercised no effect upon the result. The true theory of the process is founded on the fact, that the sugar, which disappears, is precisely equal to the united weights of the alcohol and carbonic acid; and hence the former is supposed to be resolved, during the process, into the two latter. Though a solution of pure sugar is not susceptible of the vinous fermentation, without being mixed with yeast, yet the saccharine juices of plants do not require the addition of that substance; or, in other words, they contain some principle, which, like yeast, excites the fermentative process. Thus the juice of the grape, of the apple, &c., ferments spontaneously, but not without enjoying access to the air; from which it would appear, that it must contain a principle which is convertible into yeast, or, at least, into a compound, which acquires the characteristic property of that substance, by absorbing oxygen.—The various kinds of stimulating fluids, prepared by means of the vinous fermentation, are divisible into wines, which are formed from the juices of saccharine fruits, and the various kinds of ale and beer produced from a decoction of the nutritive grains previously malted.

The juice of the grape is superior, for the purpose

of making wine, to that of all other fruits, not merely in containing a larger proportion of saccharine matter, since this deficiency may be supplied artificially, but in the nature of its acid. The chief or only acidulous principle of the mature grape, ripened in a warm climate, such as Spain, Portugal, or Madeira, is the bitartrate of potash. As this salt is insoluble in alcohol, the greater part of it is deposited during the vinous fermentation; and an additional quantity subsides, constituting the *crust*, during the progress of wine towards its point of highest perfection. The juices of other fruits, on the contrary, such as the gooseberry or currant, contain the malic or citric acids, which are soluble both in water and alcohol, and of which, therefore, they can never be deprived. Consequently, these wines are only rendered palatable by the presence of free sugar, which conceals the taste of the acid; and hence it is necessary to arrest the progress of the fermentation long before the whole of the saccharine matter is consumed. For the same reason, these wines do not admit of being long kept; for as soon as the free sugar is converted into alcohol, by the slow fermentative process, which may be retarded by the addition of brandy, but cannot be prevented, the liquor acquires a strong sour taste.

Ale and beer differ from wines, in containing a large quantity of mucilaginous and extractive matters, derived from the malt with which they are made.—From the presence of these substances, they always contain a free acid, and are greatly disposed to pass into the acetous fermentation. The sour taste is concealed, partly by free sugar, and partly by the bitter flavour of the hop, the presence of which diminishes the tendency to the formation of an acid. The fermentative process which takes place in dough mixed with yeast, and on which depends the formation of good bread, has been supposed, by some, to be of a peculiar kind, and accordingly designated by the name of the *panary fermentation*. More recent researches upon this subject, however, leave little doubt that the phenomena are to ascribed to the saccharine matter of the flour undergoing the vinous fermentation, by which it is resolved into alcohol and carbonic acid. When any liquid has undergone the vinous fermentation, or even pure alcohol, dilated with water, is mixed with yeast, and exposed in a warm place to the open air, the acetous fermentation takes place. This change is attended with an intestine movement, and the developement of heat and carbonic acid gas; the fluid, at the same time, becoming turbid, from the deposition of a peculiar filamentous matter. This process goes on tardily below 60° Fahr.; at 50°, is very sluggish; and at 32°, is wholly arrested. On the contrary, when the temperature is as high as 80°, it proceeds with vigour.

It is necessary to distinguish between the mere formation of acetic acid, and the acetous fermentation. Most vegetable substances yield acetic acid, when they undergo spontaneous decomposition; and inferior kinds of ale and beer are known to acquire acidity in a short time, even when confined in well-corked bottles. These processes, and a variety of others, however, are quite different from the proper acetous fermentation, above described, being unattended with visible movement in the liquid with the absorption of oxygen from the air, or the evolution of carbonic acid. The true acetous fermentation consists in the conversion of alcohol into acetic acid, the quantity of the latter being precisely proportional to that of the former. The nature of the chemical action is, however, at present, obscure.

It has been imagined that pure alcohol contains a greater proportional quantity of carbon and hydrogen than acetic acid; that the oxygen of the atmosphere, the presence of which is indispensable, abstracts so much of those elements, by giving rise to the formation of carbonic acid and water, as to leave the remaining carbon, hydrogen, and oxygen of the alcohol, in the precise ratio for forming acetic acid. The acetous fermentation is conducted on a large scale, for yielding the common vinegar of commerce. In France, it is prepared by exposing weak wines to the air during warm weather. In this country, it is made from a solution of brown sugar or molasses, or an infusion of malt. The vinegar thus obtained, however, always contains a large quantity of mucilaginous and other vegetable matters, the presence of which renders it liable to several ulterior changes. The putrefactive fermentation is confined to those vegetable substances, in which the oxygen and hydrogen exist, in a proportion to form water; and in such, particularly, as contain nitrogen. Those proximate principles, in which carbon and hydrogen prevail, such as the oils, resins, and alcohol, do not undergo the putrefactive fermentation; nor do acids, which contain a considerable excess of oxygen, manifest a tendency to suffer this change. The conditions requisite for enabling the putrefactive process to commence, are moisture, air, and a certain temperature. The temperature most favourable is between 60° and 100° Fahr. The products of the process may be divided into the solid, liquid, and gaseous. The liquid are chiefly water, together with a little acetic acid and oil. The gaseous products are light, carbureted hydrogen, carbonic acid, and, when nitrogen is present, ammonia. Pure hydrogen, and, probably, nitrogen, are sometimes disengaged. Another elastic principle, supposed to arise from putrefying vegetable remains, is the noxious *miasmata* of marshes. The origin of these, however, is exceedingly obscure. The solid product is a dark, pulverulent substance, consisting of charcoal, combined with a little oxygen and hydrogen, which, when mixed with a proper quantity of earth, is called *vegetable mould*.

Ferretto, in the *glass manufacture*, a substance employed to colour glass. This is made by the simple calcination of copper, but it serves for several colours. There are two ways of making it; the first is as follows: take thin plates of copper, and place them on a layer of powdered brimstone, in the bottom of a crucible; over these lay more brimstone, and over that another layer of the plates, and so on alternately till the pot is full. Cover the pot, lute it well, place it in a wind-furnace, and make a strong fire about it for two hours. When it is taken out and cooled, the copper will be found so calcined that it may be crumbled to pieces between the fingers like a friable earth; it will be of a reddish, and in some parts of a blackish colour. This must be powdered and sifted fine for use. The other way is less easy, but it makes a more valuable ferretto. It is this: make a number of stratifications of plates of copper and powdered vitriol, alternately, in a crucible, which place on the floor of the glass furnace near the eye, and let it stand there three days; then take it out, and make a new stratification with more fresh vitriol, and calcine it again as before;

repeat this operation six times, and a most valuable ferretto is produced.

Ferruginous, is applied to any thing partaking of the properties of iron, or containing particles of that metal. It is particularly applied to certain mineral springs, whose water, in their passage along the strata of the earth, meets with the ore of this metal, or with pyritæ containing it, part of which they wash off, and carry with them, and thus become impregnated with the principles thereof. Such are what we call *chalybeate waters.*

Ferrugo; the rust of iron, or a kind of calx found upon its surface. The rust of iron is astringent; it is applied medicinally.

Fesse, in *heraldry;* one of the nine honourable ordinaries of the escutcheon, which it divides horizontally in the middle, and separates the chief from the point. It is supposed to represent a broad girdle or belt of honour, such as those with which knights at arms were anciently girded. It possesses the centre of the escutcheon, and contains in breadth one third part thereof. When the fesse takes up less than its proper breadth, it is called a bar. Fesse-point is the exact centre of the escutcheon.

Festoon, in *architecture;* an ornament of carved wood, in manner of wreathes or garlands hanging down, which was anciently used at the gates of temples and other edifices.

Fever; a disease characterized by an increase of heat, an accelerated pulse, a foul tongue, and an impaired state of several functions of the body. The varieties are numerous. The principal divisions are into continued and intermittent fevers.

Continued fevers have no intermission, but exacerbations come on usually twice in one day. The genera of continued fevers are: 1. *Synocha,* or inflammatory fever, known by increased heat; pulse frequent, strong and hard; urine high coloured; senses not much impaired: 2. *Typhus,* or putrid-tending fever, which is contagious, and is characterized by moderate heat; quick, weak, and small pulse; senses much impaired, and great prostration of strength: 3. *Synochus,* or mixed fever. Intermittent fevers are known by cold, hot, and sweating stages, in succession, attending each paroxysm, and followed by an intermission or remission. There are three genera of intermitting fevers, and several varieties: 1. *Quotidiana;* a quotidian ague. The paroxysms return in the morning, at an interval of about twenty-four hours. 2. *Tertiana;* a tertian ague. The paroxysms commonly come on at mid-day, at an interval of about forty-eight hours. 3. *Quartana;* a quartan ague. The paroxysms come on in the afternoon, with an interval of about seventy-two hours. The tertian ague is most apt to prevail in the spring, and the quartan in autumn.

When these fevers arise in the spring, they are called *vernal;* and when in the autumn, they are known by the name of *autumnal.* Intermittents often prove obstinate, and are of long duration in warm climates; and they not unfrequently resist every mode of cure, so as to become very distressing to the patient, and, by the extreme debility which they thereby induce, often give rise to other chronic complaints. It seems to be pretty generally acknowledged, that marsh miasmata, or the effluvia arising from stagnant water, or marshy ground, when acted upon by heat, are the most frequent exciting cause of this fever. A watery, poor diet, great fatigue, long watching, grief, much anxiety, exposure to cold, lying in damp rooms or beds, wearing damp linen, the suppression of some long accustomed evacuation, or the recession of eruptions, have been ranked among the exciting causes of intermittents; but it is more reasonable to suppose that these circumstances act only by inducing that state of the body which predisposes to these complaints. One peculiarity of this fever is its great susceptibility of a renewal from very slight causes, as from the prevalence of an easterly wind, even without the repetition of the original exciting cause. In this circumstance, intermittents differ from most other fevers, as it is well known that, after a continued fever has once occurred, and been removed, the person so affected is by no means so liable to a fresh attack of the disorder, as one in whom it had never taken place. We have not yet attained a certain knowledge of the proximate cause of an intermittent fever, but a deranged state of the stomach and primæ viæ is that which is most generally alleged.

Each paroxysm of an intermittent fever is divided into three different stages, which are called the *cold,* the *hot,* and the *sweating stages,* or *fits.* The *cold* stage commences with languor, a sense of debility and sluggishness in motion, frequent yawning and stretching, and an aversion to food. The face and extremities become pale, the features shrink, the bulk of every external part is diminished, and the skin over the whole body appears constricted, as if cold had been applied to it. At length the patient feels very cold, and universal rigours come on, with pains in the head, back, loins, and joints, nausea and vomiting of bilious matter; the respiration is small, frequent, and anxious; the urine is almost colourless; sensibility is greatly impaired; the thoughts are somewhat confused; and the pulse is small, frequent, and often irregular. In a few instances, drowsiness and stupor have prevailed in so high a degree as to resemble coma or apoplexy; but this is by no means usual.

These symptoms abating after a short time, the second stage commences with an increase of heat over the whole body, redness of the face, dryness of the skin, thirst, pain in the head, throbbing in the temples, anxiety, and restlessness; the respiration is fuller and more free, but still frequent; the tongue is furred, and the pulse has become regular, hard, and full. If the attack has been very severe, then, perhaps, delirium will arise. When these symptoms have continued for some time, a moisture breaks out on the forehead, and, by degrees, becomes a sweat, and this, at length, extends over the whole body. As this sweat continues to flow, the heat of the body abates, the thirst ceases, and most of the functions are restored to their ordinary state. This constitutes the third stage.

When intermittents continue for any length of time, they are apt to induce other complaints, such as a loss of appetite, flatulency, scirrhus of the liver, dropsical swellings, and general debility, which, in the end, now and then prove fatal, particularly in warm climates; and, in some cases, they degenerate into continued fevers. Relapses are very common to this fever at the distance of five or six months, or even a year. Autumnal intermittents are more difficult to remove than vernal ones, and quartans more so than the other types. It is always desirable to suspend a paroxysm, if possible, not only to prevent

mischief, but also that there may be more time for the use of the most effectual remedies. When, therefore, a fit is commencing, or shortly expected, we may try to obviate it by some of those means which excite movements of an opposite description in the system: an emetic will generally answer the purpose, determining the blood powerfully to the surface of the body; or a full dose of opium, assisted by the pediluvium, &c.; ether also, and various stimulant remedies, will often succeed; but these may perhaps aggravate, should they not prevent the fit; the cold bath, violent exercise, strong impressions on the mind, &c., have likewise been occasionally employed with effect. Should the paroxysm have already come on, and the cold stage be very severe, the warm bath, and cordial diaphoretics in repeated moderate doses, may assist in bringing warmth to the surface: when, on the contrary, great heat prevails, the antiphlogistic plan is to be pursued. In the intermissions, in conjunction with a generous diet, moderate exercise, and other means calculated to improve the vigour of the system, tonics are the remedies especially relied upon. At the head of these we must certainly place the cinchona, which, taken largely in substance, will seldom fail to cure the disease, where it is not complicated with visceral affection.

Febris synocha; inflammatory fever; a species of continued fever, characterized by increased heat; pulse frequent, strong, hard; urine high-coloured; senses not impaired. This fever is so named from its being attended with symptoms denoting general inflammation in the system, by which we shall always be able readily to distinguish it from either the nervous or putrid. It makes its attack at all seasons of the year, but is most prevalent in the spring; and it seizes persons of all ages and habits, but more particularly those in the vigour of life, with strong elastic fibres, and of a plethoric constitution. It is a species of fever almost peculiar to cold and temperate climates, being rarely, if ever, met with in very warm ones, except among foreigners lately arrived; and, even then, the inflammatory stage is of very short duration, as it very soon assumes either the nervous or putrid type. The exciting causes are sudden transitions from heat to cold, swallowing cold liquors when the body is much heated by exercise, too free a use of vinous and spirituous liquors, great intemperance, violent passions of the mind, the sudden suppression of habitual evacuations, and the sudden repulsion of eruptions.

It may be doubted if this fever ever originates from personal infection; but it is possible for it to appear as an epidemic among such as are of a robust habit, from a peculiar state of the atmosphere. It comes on with a sense of lassitude and inactivity, succeeded by vertigo, rigours and pains over the whole body, but more particularly in the head and back; which symptoms are shortly followed by redness of the face and eyes, great restlessness, intense heat, and unquenchable thirst, oppression of breathing, and nausea. The skin is dry and parched; the tongue is of a scarlet colour at the sides, and furred with white in the centre; the urine is red and scanty; the body is costive; and there is a quickness, with a fulness and hardness in the pulse, not much affected by any pressure made on the artery. If the febrile symptoms run very high, and proper means are not used at an early period, stupor and delirium come on, the imagination becomes much disturbed and hurried, and the patient raves violently. The disease usually goes through its course in about fourteen days, and terminates in a crisis, either by diaphoresis, diarrhœa, hæmorrhage from the nose, or the deposit of a copious sediment in the urine; which crisis is usually preceded by some variation in the pulse.

The chief indication in synocha is to lessen the excessive vascular actions by evacuations, and the antiphlogistic regimen. Of the former, by far the most important is blood-letting. Purging is next in efficacy. As the disease advances, however, we must attempt to promote the other discharges, particularly that by the skin. The antiphlogistic regimen consists in obviating stimuli of every kind, so far as this can be done safely; impressions on the senses, particularly the sight and hearing, bodily and mental exertion, &c., must be guarded against as much as possible. The diet should be of the most sparing kind. The stimulus of heat must be especially obviated by light clothing, or even exposing the body to the air, ventilating the apartment, sprinkling the floor with vinegar and water, &c. When the head is much affected, besides the general treatment, it will be proper to take blood locally, have the head shaved and cooled by some evaporating lotion, apply a blister to the neck, and, perhaps, stimulate the lower extremities. In like manner any other organ, being particularly pressed upon, may require additional means to be used for its relief, which will be different in different cases.

Typhus; a species of continued fever, characterized by great debility, a tendency in the fluids to putrefaction, and the ordinary symptoms of fever. It is to be readily distinguished from the inflammatory by the smallness of the pulse, and the sudden and great debility which ensues on its first attack, and in its more advanced stage, by the petechiæ, or purple spots, which appear on various parts of the body, and the fetid stools which are discharged; and it may be distinguished from the nervous fever by the great violence of all its symptoms on its first coming on. The most general cause that gives rise to this disease is contagion, applied either immediately from the body of a person labouring under it, or conveyed in clothes or merchandise, &c.; but it may be occasioned by the effluvia arising from either animal or vegetable substances, in a decayed or putrid state; and hence it is, that, in low and marshy countries, it is apt to be prevalent when intense and sultry heat quickly succeed any great inundation. A want of proper cleanliness and confined air, are likewise causes of this fever; hence it prevails in hospitals, jails, camps, and on board of ships, especially when such places are much crowded, and the strictest attention is not paid to a free ventilation and due cleanliness. A close state of the atmosphere, with damp weather, is likewise apt to give rise to putrid fever. Those of lax fibres, and who have been weakened by any previous debilitating cause, such as poor diet, long fasting, hard labour, continued want of sleep, &c., are most liable to it.

On the first coming on of the disease, the person is seized with languor, dejection of spirits, great depression, and loss of muscular strength, universal weariness and soreness, pains in the head, back, and extremities, and rigours; the eyes appear full, heavy, yellowish, and often a little inflamed; the temporal arteries throb violently, the tongue is dry and parched, respiration is commonly laborious, and interrupted

with deep sighing; the breath is hot and offensive, the urine is crude and pale, the body is costive, and the pulse is usually quick, small, and hard, and now and then fluttering and unequal. Sometimes a great heat, load, and pain are felt at the pit of the stomach, and a vomiting of bilious matter ensues. As the disease advances, the pulse increases in frequency (beating often from 100 to 130 in a minute); there is vast debility, a great heat and dryness in the skin, oppression at the breast, with anxiety, sighing, and moaning; the thirst is greatly increased; the tongue, mouth, lips, and teeth are covered over with a brown or black tenacious fur; the speech is inarticulate, and scarcely intelligible; the patient mutters much, and delirium ensues. The fever continuing to increase still more in violence, symptoms of putrefaction show themselves; the breath becomes highly offensive; the urine deposites a black and fetid sediment; the stools are dark, offensive, and pass off insensibly; hæmorrhages issue from the gums, nostrils, mouth, and other parts of the body; livid spots or petechiæ appear on its surface; the pulse intermits and sinks; the extremities grow cold; hiccoughs ensue; and death at last closes the scene.

When this fever does not terminate fatally, it generally begins, in cold climates, to diminish about the commencement of the third week, and goes off gradually towards the end of the fourth, without any very evident crisis; but in warm climates it seldom continues above a week or ten days, if so long. Our opinion, as to the event, is to be formed by the degree of violence in the symptoms, particularly after petechiæ appear, although in some instances recoveries have been effected under the most unpromising appearances. An abatement of febrile heat and thirst, a gentle moisture diffused equally over the whole surface of the body, loose stools, turbid urine, rising of the pulse, and the absence of delirium and stupor, may be regarded in a favourable light. On the contrary, petechiæ, with dark, offensive, and involuntary discharges by urine and stool, fetid sweats, hæmorrhages and hiccoughs denote the almost certain dissolution of the patient. The appearances usually perceived on dissection are inflammations of the brain and viscera, but more particularly of the stomach and intestines, which are now and then found in a gangrenous state. In the muscular fibres there seems likewise a strong tendency to gangrene.

In the very early period of typhus fever, it is often possible, by active treatment, to cut short the disease at once; but where it has established itself more firmly, we can only employ palliative measures to diminish its violence, that it may run safely through its course. Among the most likely means of accomplishing the first object is an emetic. Attention should next be paid to clear out the bowels by some sufficiently active form of medicine; and, as the disease proceeds, we must keep up this function, and attempt to restore that of the skin, and the other secretions, as the best means of moderating the violence of vascular action. The general antiphlogistic regimen is to be observed in the early part of the disease, as explained under *synocha*. In cases where the skin is uniformly hot and dry, the abstraction of caloric may be more actively made by means of the cold affusion, that is, throwing a quantity of cold water on the naked body of the patient; which measure has sometimes arrested the disease in its first stage; and, when the power of the system is less, sponging the body occasionally with cold water, medicated, perhaps, with a little salt or vinegar, may be substituted as a milder proceeding. But, where the evolution of heat is even deficient, such means would be highly improper; and it may be sometimes advisable to employ the tepid bath, to promote the operation of the diaphoretic medicines. If, under the use of the measures already detailed, calculated as they are to lessen the violence of vascular action, the vital powers should appear materially falling off, recourse must then be had to a more nutritious diet, with a moderate quantity of wine, and cordial or tonic medicines.

There is generally an aversion to animal food, whence the mucilaginous vegetable substances, as arrow-root, &c., rendered palatable by spice or a little wine, or sometimes mixed with milk, may be directed as nourishing and easy of digestion. If, however, there be no marked septic tendency, and the patient cloyed with these articles, the lighter animal preparations, as calves-foot jelly, veal-broth, &c., may be allowed. The extent to which wine may be carried, must depend on the urgency of the case, and the previous habits of the individual; but it will commonly not be necessary to exceed half-a-pint, or a pint at most, in the 24 hours; and it should be given in divided portions, properly diluted, made, perhaps, into negus, whey, &c., according to the liking of the patient. The preference should always be given to that which is of the soundest quality, if agreeable; but where wine cannot be afforded, good malt liquor, or mustard whey, may be substituted.

Some moderately stimulant medicines, as ammonia, aromatics, serpentaria, &c., may often be used with advantage, to assist in keeping up the circulation; also those of a tonic quality, as columba, cusparia, cinchona, &c., occasionally in their lighter forms; but more especially the acids. These are, in several respects, useful: by promoting the secretions of the primæ viæ, &c., they quench thirst, remove irritation, and manifestly cool the body; and in the worst forms of typhus, where the putrescent tendency appears, they are particularly valuable from their antiseptic power; they are also decidedly tonic, and, indeed, those from the mineral kingdom powerfully so. These may be given freely as medicines, the carbonic acid also in the form of brisk fermenting liquors; and the native vegetable acids, as they exist in ripe fruits, being generally very grateful, may constitute a considerable part of the diet. In the mean time, to obviate the septic tendency, great attention should be paid to cleanliness and ventilation, and keeping the bowels regular by mild aperients, or clysters of an emollient or antiseptic nature; and where aphthæ appear, acidulated gargles should be directed. If the disease inclines more to the nervous form, with much mental anxiety, tremors, and other irregular affections of the muscles, or organs of sense, the antispasmodic medicines may be employed with more advantage, as ether, camphor, musk, &c., but particutarly opium, which should be given in a full dose, sufficient to procure sleep, provided there be no appearances of determination of blood to the head; and it may be useful to call a greater portion of nervous energy to the lower extremities by the pediluvium, or other mode of applying warmth, or occasionally by synapisms, not allowing these to

produce vesication. But if there should be much increased vascular action in the brain, more active means will be required; even the local abstraction of blood, if the strength will permit; and it will be always right to have the head shaved, and kept cool by some evaporating lotion, and a blister applied to the back of the neck. In like manner, other important parts may occasionally require local means of relief. Urgent vomiting may, perhaps, be checked by the effervescing mixture; a troublesome diarrhœa by small doses of opium, assisted by aromatics, chalk, ond other astringents, or sometimes by small doses of ipecacuanha; profuse perspirations by the *infusum rosæ*, a cooling regimen, &c.

Nervous Fever; a variety of the *typhus mitior* of Cullen, but by many considered as a distinct disease. It mostly begins with loss of appetite, increased heat and vertigo; to which succeed nausea, vomiting, great languor, and pain in the head, which is variously described, by some like cold water pouring over the top; by others, a sense of weight. The pulse, before little increased, now becomes quick, febrile, and tremulous; the tongue is covered with a white crust, and there is great anxiety about the præcordia. Towards the seventh or eighth day, the vertigo is increased, and tinnitus aurium, cophosis, delirium, and a dry and tremulous tongue take place. The disease mostly terminates about the fourteenth or twentieth day.

Dengue Fever. This name has been given to a disease which appeared in the years 1827 and 1828, in the West Indies, and in the southern States of North America. It has also been called the *dingee, the danga*, the *dandy*, the *bouquet*, and the *bucket* fever. This disease was remarkable for the suddenness of its attack, the great numbers affected, the severity of the symptoms, and the rareness of death from it. It would seem, from the reports of those who have seen most of this disease, and whose judgment may be relied on, that the *dengue* has some affinities with the yellow fever. The symptoms, as noticed in the Havanna, were first great languor, chilliness, and pain in the tendons of the smaller joints: following these were burning heat and redness of the skin, pains in the muscles of the limbs, or pain in the forehead, and a loathing or vomiting of whatever was taken into the stomach. The fever continued for one, two, or three days, and then usually terminated with a free sweating, which freed the patient, likewise, from his pains. But many, after leaving their beds, suffered by a renewal of their pains, which, in some, have become chronic; others have also had a renewed attack of the fever. "The most usual mode of attack, however," says Dr. Stedman, of Santa Cruz, "which appears not a little singular, was the following: A person in perfect health would suddenly feel a stiffness, amounting almost to pain, in one of his fingers, and most frequently his little finger. The stiffness increased, and was accompanied with an intense degree of pain, which spread rapidly over the whole hand, and up the arm to the shoulder. The fingers in both hands, in a few hours, became swelled, stiff, and painful, preventing all attempts at bending the joints." To this succeeded restlessness, depression of spirits, nausea, vomiting, shivering, great heat, intense headache, and most acute pain in every joint. The most distressing symptoms were intense pain in the eye-balls and back, the eyes seeming to the patient enlarged, filling the sockets, and as if ready to burst. Quite a remarkable symptom was the feeling of intense cold, while, at the same time, the skin was intensely hot. These symptoms continued from 24 to 36 hours. The patient now remained languid, irritable, and restless for about three days, when it was not uncommon for a new attack to come on, accompanied by an efflorescence, beginning at the palms of the hands, and extending thence over the whole body. Secondary symptoms, consisting principally in pain and stiffness of the limbs and body, followed, which, in many cases, continued even weeks, and made the patient most uncomfortable. Sometimes there was distressing itching; and, in some cases, there was swelling of the prepuce and scrotum, and, in others, a discharge from the urethra, resembling gonorrhœa. Dr. Stedman considers the disease, contagious. The treatment was, for the most part, antiphlogistic. Such means were used as would hasten the sweating stage, evacuate the bowels, and render the patient most comfortable. Where these means failed, the more active depleting means were resorted to, and much relief of local suffering was afforded by the use of blisters and stimulating embrocations, mustard poultices, and the like. The latter was applied to the temples, to relieve the pain in the eye-balls, to the back, the back of the neck, &c., as indicated, and always with advantage. Dr. Stedman found benefit from blood-letting, in some severe cases.

Synochus; a mixed fever; a species of continued fever, commencing with symptoms of synocha, and terminating in typhus, the former being apt to preponderate at its commencement, and the latter towards its termination. Every thing which has a tendency to enervate the body may be looked upon as a remote cause of this fever; and, accordingly, we find it often arising from great bodily fatigue. too great an indulgence in sensual pleasures, violent exertions, intemperance in drinking, and errors in diet, and now and then likewise from the suppression of some long accustomed discharge. Certain passions of the mind (such as grief, fear, anxiety, and joy) have been enumerated among the causes of fever, and, in a few instances, it is probable they may have given rise to it; but the concurrence of some other powers seems generally necessary to produce this effect.

The most usual and universal cause of this fever is the application of cold to the body; as, for instance, when the body is deprived of a part of its accustomed clothing, or a particular part is exposed while the rest is kept at its usual warmth, or a sudden and general exposure to cold takes place when the body is heated much above its usual temperature. Another frequent cause of fever seems to be breathing air contaminated by the vapours arising either directly or originally from the body of a person labouring under the disease. A peculiar matter is supposed to generate in the body of a person affected with fever, and this, floating in the atmosphere, and being applied to one in health, will, no doubt, often cause fever to take place in him; which has induced many to suppose, that this infectious matter is produced in all fevers whatever, and that they are all more or less contagious. The effluvia arising from the human body, if long confined to one place, without being diffused in the atmosphere, will, it is well known, acquire a singular virulence, and will, if applied to the bodies of men, become the cause of

fever. Exhalations, arising from animal or vegetable substances in a state of putrefaction, have been looked upon as another general cause of fever; marshy or moist grounds, acted upon by heat for any length of time, usually send forth exhalations, which prove a never-failing source of fever, particularly in warm climates.

An attack of this fever is generally marked by the patient's being seized with a considerable degree of languor or sense of debility, together with a sluggishness in motion, and frequent yawning and stretching; the face and extremities at the same time become pale, and the skin over the whole surface of the body appears constricted; he then perceives a sensation of cold in his back, passing from thence over his whole frame; and, this sense of cold continuing to increase, tremours in the limbs and rigours of the body succeed. There is also a loss of appetite, want of taste in the mouth, slight pains in the head, back, and loins, with small and frequent respirations. The sense of cold and its effects, after a little time, become less violent, and are alternated with flushings; and at last, going off altogether, they are succeeded by great heat diffused generally over the whole body; the face looks flushed, the skin is dry, as likewise the tongue; universal restlessness prevails, with a violent pain in the head, oppression at the chest, sickness at the stomach, and an inclination to vomit. There is likewise a great thirst and costiveness, and the pulse is full and frequent, beating, perhaps, 90 or 100 strokes in a minute. When the symptoms run very high, and there is a considerable determination of blood to the head, delirium will arise. In this fever, as well as most others, there is generally an increase of symptoms towards evening.

As a fever once produced will go on, although its cause be entirely removed, and as the continued or fresh application of a cause of fever will neither increase that which is already produced, nor occasion a new one, there can be no certainty as to the duration of fever; and it is only by attending to certain appearances or changes which usually take place on the approach of a crisis, that we can form any opinion or decision. The symptoms pointing out the approach of a crisis, are, the pulse becoming soft, moderate, and near its natural speed; the tongue losing its fur, and becoming clean, with an abatement of thirst; the skin being covered with a gentle moisture, and feeling soft to the touch; the secretory organs performing their several offices; and the urine depositing flaky crystals of a dirty red colour, and becoming turbid on being allowed to stand any time.

A simple continued fever terminates always by a regular crisis, in the manner before mentioned, or, from the febrile matter falling on some particular parts, it excites inflammation, abscess, eruption, or destroys the patient. This disease being of a mixed nature, the treatment must be modified accordingly. In the beginning, the same plan is to be pursued as in synocha, except that we must be more sparing in the use of the lancet, in proportion as there is less power in the system to maintain the increased action of the heart and arteries; although, if any important part should be much affected, we must act more vigorously, to prevent its disorganization, and the consequent destruction of life. When the character of the disease is changed, the remedies will be such as are pointed out under the head of *Typhus*.

FIBRE, in *anatomy*; a simple filament which is supposed to consist of earthy particles, connected together by an intermediate gluten. Fibres are distinguished, according to their position and course, into direct, transverse, and oblique; and by their different arrangement are formed the membranes, muscles, vessels, nerves, &c. Those fibres which compose muscles are called muscular; those which form nerves, nervous; the rest are distinguished into *carneous* or fleshy, and *osseous* or bony.

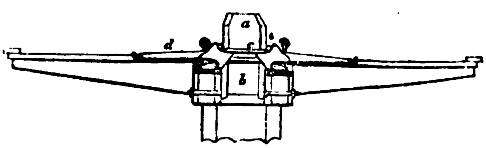
FIBRIN; a peculiar organic compound, found both in vegetables and animals. It is a soft solid, of a greasy appearance, insoluble in water, which softens in the air, becoming viscid, brown, and semi-transparent. On hot coals it melts, throws out greasy drops, crackles, and evolves the smoke and odour of roasting meat. It is procured, in its most characteristic state, from animal matter. It exists in chyle; it enters into the composition of blood; and it forms the chief part of muscular flesh; and hence it must be regarded as the most abundant constituent of the soft solids of animals. According to the analysis of MM. Gay-Lussac and Thénard, it is composed of carbon 53.36, nitrogen 19.934, oxygen 19.685, and hydrogen 7.021

FIBULA, in *anatomy*; a long bone of the leg situated on the outer side of the tibia, and forming, at its lower end, the outer ancle.

FIBULA, in *surgery*; a needle with which wounds are sewed together.

FIBULA, in *architecture*; an iron cramp with which square stones are held together.

FID; an instrument for supporting the upper mast of a ship, by means of levers adapted to frames or carriages of iron, attached to the upper cross-trees. The contrivance we have represented beneath has been the source of a large fortune to its inventor.



The heel of the topmast is shown at *a*, and *d* represents the levers, on the shorter arms of which the fid-plate, *c*, rests. The top of the lower mast is shown at *b*. When the mast is to be lowered, the longer arms of the levers are pressed downwards and the fid-plate removed.

FIELD, in *heraldry*; the whole surface of the shield or escutcheon; so called, probably, because it bore the achievements which were worn in the field of battle.

FIELD PIECES; small cannons, from 3 to 12 pounders, carried with an army. *Field staff*; a staff carried by the gunners, about the length of a halbert, with a spear at one end, having on each side ears screwed on, like the cock of a matchlock, into which the bombardiers screw lighted matches when they are upon command; and then the field staffs are said to be armed.

FIELD WORKS, in *fortification*, are those thrown up by an army in besieging a fortress, or by the besieged to defend the place; as the fortifications of camps, highways, &c.

FIFE; a wind instrument of the martial kind, consisting of a short, narrow tube, with holes disposed along the side, for the regulation of its tones.

FIFTH, in *music*; a distance comprising four diatonic intervals, that is, three tones and a half. *Fifth sharp* is an interval consisting of eight semitones.

FIGURATE NUMBERS; an arithmetical amusement much in vogue at the beginning of the seventeenth century. Jac. Bernouilli, and particularly Wallis in his *Arith. Infinit.*, and L'Huilier, in his *Algebra*, have made it a subject of investigation. These numbers are formed by the terms of arithmetical series, of all sorts, in which the first member is always unity. For example:—

I.—1,	2,	3,	4,	5,	6,	&c.
II.—1,	3,	6,	10,	15,	21,	&c.
III.—1,	4,	9,	16,	25,	36,	&c.
IV.—1,	5,	12,	22,	35,	51,	&c.

Those in the second row are called *triangular* numbers, because their units may be arranged in pure equilateral triangles; the members of the third row are called *square* numbers; those of the fourth *pentagonal*, &c.; and so there are also *hexagonal, heptagonal*, and, in general, *polygonal* numbers. If the terms of the polygonal series are again added, in succession, we obtain other orders, as the members of each of the rows are called; thus,

a.—1,	3,	6,	10,	15,	21,	&c.
b.—1,	4,	10,	20,	35,	56,	&c.
c.—1,	5,	14,	30,	55,	91,	&c.
d.—1,	6,	18,	40,	75,	126,	&c.,

are pyramidal numbers, because, by placing over one another the polygonal numbers in the order in which they are added, so that the smaller come over the next larger of the same sort, regular pyramids are formed. Thus the members of the row *a* form triangular, of the row *b* quadrangular, and of the row *c* pentagonal pyramids.

FILAMENTS, in *anatomy*; the small fibres or threads which compose the texture of the muscles.

FILE, in *heraldry*; the straight line in a label, from which the several points issue.

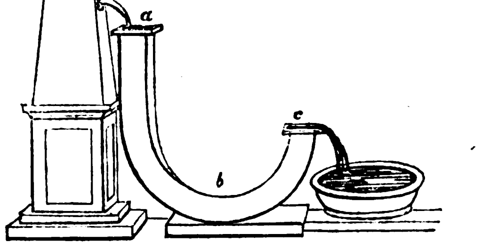
FILE, in *military* language; any number of men drawn up in a straight line behind each other.

FILLAGREE WORK; a kind of ornamental work in gold or silver, wrought delicately, in the manner of little threads or grains, or of both intermixed. In Sumatra manufactures of this kind are carried to very great perfection, though the tools made use of are very coarse and clumsy. The workmen melt the gold in a crucible of their own forming, and, instead of bellows, they blow with their mouths through a piece of bamboo. They draw and flatten the wire in a manner similar to that adopted by Europeans. It is then twisted, and thus a flower, or the shape of a flower, is formed. A pattern of the flowers or foliage is prepared on paper, of the size of the gold plate on which the fillagree is to be laid. According to this they begin to dispose on the plate the larger compartments of the foliage, for which they use plain flat wire of a larger size, and fill them up with the leaves. A gelatinous substance is used to fix the work, and, after the leaves have been placed in order, and stuck on, bit by bit, a solder is prepared of gold filings and borax, moistened with water, which is strewed over the plate; and, after being put into the fire a short time, the whole becomes united. When the fillagree is finished, it is cleansed with a solution of salt and alum in water. The Chinese make most of their fillagre of silver, which looks very well, but has not the extraordinary delicacy of Malay work.

FILLET, in *architecture*, is a small square or flat moulding. (See ARCHITECTURE.)

FILTER. The very great utility of filters for domestic purposes must be evident, as a fluid fit for culinary use can through their means be obtained from any source, however muddy or impure, and it must be a desideratum in such contrivances to combine the cheap, the durable, and the efficacious;—to this end a vast variety have been invented, many possessing great advantages. The filter in most general use is a basin formed of some porous kind of stone, and supported over any convenient vessel to catch the percolating fluid. The foul water, being poured into the basin, insinuates itself by slow degrees through the minute pores of the stone, and is collected, drop by drop, in the receptacle placed beneath. This apparatus answers the purpose perfectly well for a time, but has its defects; the constant accumulation of the impurities, after a little while, chokes up the pores of the stone, and, although at first this may be amended by washing, yet ultimately the fine particles insensibly sink down into the stone, the pores become filled, and no water passes. There is also an error noticeable in the form of the vessel, which is in general hemispherical; in this the pressure of the fluid is greatest at the lowest points, and gradually diminishes in every other part; so that, unless the pressure is greater at the centre than it ought to be, scarcely any water will pass through the other parts. A more eligible form would be that of a cylinder, formed either of earthenware or metal, with a circular plate of the filtering stone cemented into the middle; by this means the pressure on all parts would be equal: it would possibly possess another advantage, that of cleansing itself; for, when the water ceased to flow with freedom on the one side, it might be inverted, and then the mere act of filtration would remove the matter deposited on the other side.

One of the simplest modes of constructing a useful filter is shown in the diagram beneath.



It consists of a tube, *a b c*, bent like a syphon, but inverted. In this is placed a quantity of sand, through which the filtration occurs. By its gravity it descends from *a* to *b*, and, as fluids always have a tendency to

a state of equilibrium, it rises in the opposite arm of the bent tube, whence it passes out in a pure state. A small piece of wood, with holes pierced through it, should be placed on the sand at the larger end.

A very clean and useful patent filter may now be described. One of the leading features of this invention appears to be the construction of vessels which are to be employed for filtering water for domestic uses, by combining slabs of slate, and the other is passing the water upwards in a zigzag course through layers or beds of sand and other purifying matters.

These slabs of slate are to be cemented together at the joints, by a mixture of white lead, or a strong mortar made of lime; and the slabs are to be farther supported and braced together, to prevent their separating, by rods of iron passed through the vessel, and secured by nuts screwed on the outsides.

The form of the vessel is proposed to be square, or at least rectangular, and twice as high as the breadth of the base, the internal part being divided into five compartments, by gratings or perforated plates. The water is to be introduced into the lowest compartment, by a pipe leading from a reservoir placed in an elevated situation, in order that the pressure from above may cause the water to rise through the filter to the top.

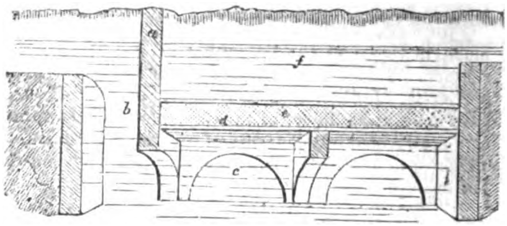
The lowest compartment, or receiving vessel, is covered by a grating, upon which, occupying the second compartment, a quantity of sand is placed. The water is therefore to percolate through the sand upward, and deposit any foul matter with which it may be impregnated in the bed of sand. Above the second compartment a plate is fixed, with conical holes in the centre, through which the water is made to pass, by the upward pressure, into the third compartment, which is likewise filled with sand. The part above this third compartment is perforated towards one side only, so that the water, in passing upwards, has to proceed through the bed of sand partly in a horizontal direction.

The fourth compartment is occupied with sand and carbonaceous matter, such as broken pieces of charcoal, burnt brick, or unglazed pottery ware, which not only takes up the foul matter mechanically, but also acts chemically upon the water, to sweeten and purify it from any animal matter which it may contain. The plate above the compartment is perforated with conical holes towards the opposite sides of the lower plate, for the purpose, as before stated, of causing the water to percolate through the bed, partly in a horizontal direction, and, by thus giving it a zigzag course, to bring it in contact with a more extended bed of the purifying material than it would be exposed to if it passed directly upwards.

The fifth compartment contains broken pieces of slag from the foundry; and from this compartment, which is at the top of the filtering vessel, the purified water is to be drawn off for use.

In constructing a filtering apparatus of large capacity, it is proposed to make its sides with brick, or in some cases with iron, properly secured together; but the plan of a slate frame secured by external bars of iron is by far the most cleanly that can be devised.

A process for filtering water on the large scale has been some time employed on the banks of the Seine, for the use of Paris; and an arrangement producing similar results, though on a comparatively small scale, is now going on at Hammersmith. We give a diagram of a cheap apparatus for extensive filtration beneath.



The wall *a* serves to separate the water to be filtered from the reservoir holding the pure water. The fluid, descending at *b*, enters beneath the arches *c*. These serve to support an extensive frame-work, either of wood or metal, on which are placed large fragments of stone. The pieces are diminished in size in ascending towards the upper strata, till, on arriving at about *e*, sand takes the place of larger masses. A second frame-work, or sheet of canvass, separates the filtering materials from the pure water at *f*.

Finale; the concluding part of a musical composition; for instance, of a quartetto, of a symphony, of any act of an opera, of a ballet, &c. It consists of compositions of various characters. The finale, in instrumental pieces, has mostly a character of vivacity, and requires a quick movement and lively performance. In the opera, the finale mostly consists of a series of compositions for many voices, and of different character and different time and movement.

Fine Arts. See Arts, Fine.

Finger-Board; that thin, black covering of wood laid over the neck of a violin, violoncello, &c., and on which, in performance, the strings are pressed by the fingers of the left hand, while the right manages the bow.

Fingering; disposing of the fingers in a convenient, natural, and apt manner in the performance of any instrument, but more especially the organ and piano-forte. Good fingering is one of the first things to which a judicious master attends. It is, indeed, to this that the pupil must look as the means for acquiring a facile and graceful execution, and the power of giving passages with articulation, accent, and expression. Easy passages may be rendered difficult, and difficult ones impracticable, by bad fingering; and, though there are many arrangements of notes which admit of various fingering, still, even in these, there is always one best way of disposing of the hand, either with regard to the notes themselves, or those which precede or follow them. But there are an infinite number of possible dispositions of notes, which can only be fingered in one particular way; and every attempt at any other is but endangering the establishment of some awkwardness, which the practitioner will have to unlearn before he can hope to attain the true fingering. Hence it is obvious that no qualification requisite to good performance is of more importance to the learner than that of just fingering, and that, whatever talents and assiduity may be able to achieve independent of instruction, in this great particular the directions of a skilful master are indispensable.

Finery; the furnace in which the operation of refining metals is performed.

Finite, in *mathematics*; an epithet for a series, line, &c., which is bounded or limited in extent, duration, &c., in contradistinction to infinite.

Fire. The all-consuming energy of fire, the first and most important agent of civilization, the similarity of its effects to those of the sun, its intimate connection with light, its terrible and yet beneficent power, the beauty of the constantly changing flame, its many colours and shapes,—easily explain how it happened that, in times when cause and effect, form and essence, were not yet distinctly separated, fire became an object of religious veneration, a distinguished element in mythology, an expressive symbol in poetry, and an important agent in the systems of cosmogony. It obtained a place among the elements, and was for a long time considered to be a constituent part in the composition of all bodies, and to require only the concurrence of favourable circumstances to develope its activity. It was early thought that fire showed itself in its elementary form in electrical phenomena. At a later period, it was believed to be the source of all chemical action, and, as such, was called *phlogistique*. It was finally confounded with light, and became, as it were, the principal agent of the universe. Those agents, differing in their qualities from other bodies, and sometimes called *imponderable* agents, under whatever light they may be viewed, open a vast field for speculation; and it is not surprising that some philosophers should have seen only different modifications of the same matter, where others have thought to recognise the influence of different kinds of matter; thus the effects of fire have been attributed to a vibratory motion of the particles of matter, or to the undulations of ether. When natural philosophy was treated in the schools, theories were adopted to which little attention is paid in the present age, when all science is founded on facts and observations. Caloric, be it a material agent or the consequence of vibratory motion, is at present considered the cause of the phenomena which were formerly ascribed to fire. Nevertheless, the nature of the one is as unknown to us as that of the other was to the ancients. The substitution of one of these terms for the other has, however, introduced a greater precision of language, and cause and effect are no longer confounded under the same name. (See Caloric and Combustion.)

The word *fire*, with different epithets, or *ignis* (Latin), has been used for the spontaneous or casual combustion of gaseous substances. Such is the *ignis fatuus*, the Jack-with-the-lantern, or Will-with-the-wisp, observed in places where animal matter is in a state of putrefaction. Such are also the exhalations called *fire-damps*, which is indeed a most unphilosophical term, as there is no damp in the matter. They are frequently seen in coal mines, and are kindled by the approach of flame, and produce terrible explosions, which may be prevented by currents of air, or more completely by Sir Humphry Davy's safety-lamp. The former phenomenon is attributed to phosphureted hydrogen gas, which takes fire on exposure to the atmosphere, and the latter to carbureted hydrogen gas, which, when mixed with a certain proportion of atmospheric air, and brought into contact with burning bodies, explodes. (See Mine.)

The warm springs, the existence of extinct volcanoes, the effects of those still in activity, and the fact that the temperature of the earth becomes warmer the deeper we descend, have induced many philosophers to adopt the idea of subterranean fires, or of a central fire. According to the former hypothesis, there are combustible materials, in a state of ignition, in the bowels of the earth, which produce the heat indispensable for the production of the above-mentioned phenomena. The latter hypothesis supposes that the globe was once in a state of igneous fusion, that the surface has gradually become solid by cooling, and that the interior of the earth is still liquid and hot, and may remain so for ever, if the heat received from the sun should continue.

Fire-Balls. It is a fact that has been long known, that clays and also several other incombustible substances, when mixed with sea-coal in certain proportions, cause the coal to give out more heat in its combustion than it can be made to produce when it is burned pure or unmixed; but the cause of this increase of heat does not appear to have been yet investigated with that attention which so extraordinary and important a circumstance seems to demand.

Daily experience teaches us that all bodies, those which are incombustible as well as those which are combustible and actually burning, throw off in all directions heat, or rather calorific (heat-making) rays, which generate heat wherever they are stopped or absorbed; but common observation was hardly sufficient to show any perceptible difference between the quantities of calorific rays thrown off by different bodies when heated to the same temperature, or exposed in the same fire, although the quantities so thrown off might be, and probably are, very different.

It has lately been ascertained that when the sides and back of an open chimney fire-place in which coals are burned are composed of fire-bricks, and heated red hot, they throw off into the room incomparably more heat than all the coals that could possibly be put into the grate, even supposing them to burn with the greatest possible degree of brightness. Hence it appears that a red-hot burning coal does not send off near so many calorific rays as a piece of red-hot brick or stone of the same form and dimensions; and this interesting discovery will enable us to make some very important improvements in the construction of our fire-places, and also in the management of our fires.

The fuel, instead of being employed to heat the room directly or by the direct rays from the fire, should be so disposed, or placed, as to heat the back and sides of the grate, which must be always constructed of fire-brick or fire-stone, and never of iron or of any other metal. Few coals, therefore, when properly placed, make a much better fire than a larger quantity; and shallow grates, when they are constructed of proper materials, throw more heat into a room, and with a much less consumption of fuel, than deep grates; for a large mass of coals in the grate arrests the rays which proceed from the back and sides of the grate, and prevents their coming into the room; or, as fires are generally managed, it prevents the back and sides of the grate from ever being sufficiently heated to assist much in heating the room, even though they be constructed of good materials, and large quantities of coals be consumed in them.

It is possible, however, by a simple contrivance, to make a good and economical fire in almost any grate, though it would always be advisable to construct fire-places on good principles, or to improve them by judicious alterations, rather than to depend on the use of additional inventions for correcting their defects.

To make a good fire in a bad grate, the bottom of the grate must first be covered with a single layer of

balls, made of good fire-bricks, or artificial fire-stone, well burnt, each ball being perfectly globular, and about 2½ or 2¾ inches in diameter. On this layer of balls the fire is to be kindled, and, in filling the grate, more balls are to be added with the coals that are laid on; care must, however, be taken in this operation to mix the coals with the balls well together, otherwise, if a number of the balls should get together in a heap, they will cool, not being kept red-hot by the combustion of the surrounding fuel, and the fire will appear dull in that part; but if no more than a due proportion of the balls are used, and if they are properly mixed with the coals, they will all, except it be those perhaps at the bottom of the grate, become red hot, and the fire will not only be very beautiful, but it will send off a vast quantity of radiant heat into the room, and will continue to give out heat for a great length of time. It is the opinion of several persons, who have for a considerable time practised this method of making their fires, that more than one-third of the fuel usually consumed may be saved by this simple contrivance. It is very probable that, with careful and judicious management, the saving would amount to one-half, or fifty per cent.

As these balls, made in moulds and burnt in a kiln, would cost very little, and as a set of them would last a long time, probably several years, the saving of expense in heating rooms by chimney fires with bad grates, in this way, is obvious; but still it should be remembered that a saving quite as great may be made by altering the grate, and making it a good fire-place.

In using these balls, care must be taken to prevent their accumulating at the bottom of the grate; as the coals go on to consume, the balls mixed with them will naturally settle down towards the bottom of the grate, and the tongs must be used occasionally to lift them up. And, as the fire becomes low, it will be proper to remove a part of them, and not to replace them in the grate till more coals are introduced: a little experience will show how a fire made in this manner can be managed to the greatest advantage, and with the least trouble.

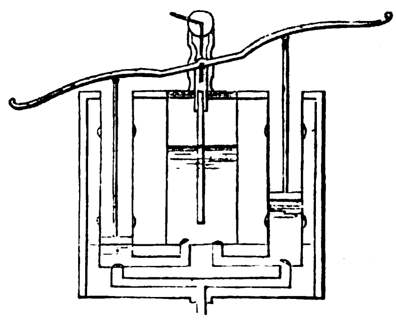
Balls made of any kind of well-burnt hard brick, though not equally durable with fire-brick, will answer very well, provided they are made perfectly round; but, if they are not quite globular, their flat sides will get together, and, by obstructing the free passage of the air amongst them and amongst the coals, will prevent the fire from burning clear and bright.

The best composition for making these balls, when they are formed in moulds, and afterwards dried and burnt in a kiln, is pounded crucibles, mixed up with moistened Stourbridge clay; but good balls may be made with any very hard burnt common bricks, reduced to a coarse powder, and mixed with Stourbridge clay, or even with common clay. The balls should always be made so large as not to pass through between the front bars of a grate.

These balls have one advantage which is peculiar to them, and which might perhaps recommend the use of them to the curious, even in fire-places constructed on the best principles; they cause cinders to be consumed almost entirely,—and even the very ashes may be burnt, or made to disappear, if care be taken to throw them repeatedly upon the fire when it burns with intense heat. It is not difficult to account for this effect in a satisfactory manner; and in accounting for it we shall explain a circumstance on which it is probable that the great increase of the heat of an open fire, where these balls are used, may in some measure depend. The small particles of cinder which, in a common fire, fall through the bottom of the grate and escape combustion, when these balls are used, can hardly fail to fall and lodge on some of them; and, as they are intensely hot, these small bodies which alight upon them in their fall, are soon heated red hot, and disposed to take fire and burn; and as fresh air from below the grate is continually making its way upwards amongst the balls, every circumstance is highly favourable to the rapid and complete combustion of these small inflammable bodies. But, if these small pieces of coal and cinder should in their fall happen to alight on the metallic bars which form the bottom of the grate (as these bars are conductors of heat, and on account of that circumstance as well as of their situation below the fire, they never can be made very hot), any small particle of fuel that happens to come in contact with them not only cannot take fire, but would cease to burn should it arrive in a state of combustion.

Fire-Dress; a new invention of the Chevalier Aldini, which is stated to be an effectual protection against fire, in the reports of committees of the highest respectability appointed to examine it at Paris. It enables the wearer (as has been demonstrated by public experiments) to approach with impunity, or even to pass through a fierce flame, to rescue lives or portable valuable property, or to use means for the extinction of fire. It consists of an exterior light armour of metallic gauze, and of an inner covering of a material which is a slow conductor of heat. Amongst flexible fibrous substances capable of being spun and woven into tissues, the asbestos possesses pre-eminently the property of slowly conducting heat; but the other fibrous matters in common use for the purpose of clothing, such as wool, cotton, &c., may, by immersion in certain saline solutions, be rendered very imperfect conductors, so as to fit them very sufficiently for preventing the transmission of injurious heat to the body, during a temporary exposure of some minutes to the action of flame on the outward covering of wire gauze.

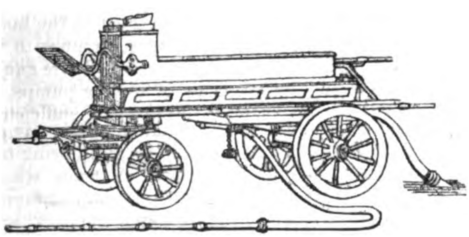
Fire-Engines are a species of forcing pumps, in which the water is subjected to pressure sufficiently strong to raise it to the required height. A fire engine of the best form is shown beneath.



In order to remedy the intermission of the jets which would result from the simple forcing pump, and to produce the discharge of a continuous stream, a vessel filled with air is attached to the engine. The water is forced into this vessel by two forcing pumps, and the air contained therein being condensed, it reacts on the water with a power proportioned to the

condensation. Thus, if the air is condensed one-third, its elasticity will be three times greater than that of the atmosphere, and it will raise water in a tube to the height of 66 feet. The spouting pipe for directing the water upon the fire proceeds from the common air vessel. The handles are so disposed that while the piston of one pump is up, that of the other is down; and they are elongated for the purpose of enabling a great number of men to work them at the same time, so that they may throw a large quantity of water. In Newsham's engines, two cylinders, constructed like forcing pumps, are worked by the reciprocating motions of transverse levers, to which the handles are attached. In this way the water is forced into the air vessel, from which it afterwards spouts through a moveable pipe. In some engines, a single cylinder is used, the piston rod passing through a tight collar, and alternately receiving and expelling the water at each end of the cylinder. In Rowntree's engine, and some others, a part of the inside of a cylinder is traversed by a partition like a door hinged upon the axis of the cylinder, which drives the water successively from each side of the cylinder into the air-vessel. The *hose*, a long flexible tube, made of leather, is of great use in carrying the spouting orifice near to the flames, and thus preventing the water from being scattered too soon. It also serves an important purpose in bringing water from distant reservoirs, by suction created in the pumps of the engine.

Having described several forms of the fire-engine, we may now direct the reader's attention to an external view of the one usually employed. It consists of two cylinders concealed in a box, and, as is shown in the previous page, provided with pistons fitting air-tight. The hose is seen to pass from beneath, and the jet-pipe is a long tube for directing the water. It is shown on the ground.



The steam fire-engine by Mr. Braithwaite is of recent invention. It is an ingenious application of the moving power of steam to the working of fire-engines. The mechanical arrangement consists of two cylinders, the one of 7 inches diameter, being the steam cylinder, and the other of 6½ inches diameter, being the water pump. By the horizontal position of the two cylinders, the parallel motion is easily produced. The boiler is on the construction and principle of Braithwaite and Ericson's patent steam generator. This engine will deliver about 9000 gallons an hour to an elevation of 90 feet, through an adjutage of ⅞ inch. The time of getting the machine into action, from the moment of igniting the fuel (the water being cold), is 18 minutes. As soon as an alarm is given, the fire is kindled, and the bellows, attached to the engine, are worked by hand. By the time the horses are harnessed in, the fuel is thoroughly ignited, and the bellows are then worked by the motion of the wheels of the engine. By the time of arriving at the fire, preparing the horses, &c., the steam is ready. The expense of fuel is stated to be sixpence per hour.

Fire, Greek, was invented in the 7th century. When the Arabs besieged Constantinople in 668, the Greek architect Callinicus of Heliopolis deserted from the caliph to the Greeks, and took with him a composition which, by its wonderful effects, struck terror into the enemy, and forced them to take to flight. Sometimes it was wrapped in flax attached to arrows and javelins, and so thrown into the fortifications and other buildings of the enemy, to set them on fire. At other times, it was used in throwing stone balls from iron or metallic tubes against the enemy. The use of this fire continued at least until the end of the 13th century: but no contemporary writer has handed down to us any accurate account of its composition. To judge from its effects, neither naphtha, sulphur, nor rosin, was a principal ingredient; but saltpetre probably was. It does not appear, from the accounts of the ancients, that it burned *under* water, as has been supposed, but merely that it burned *upon* it. Cardian invented a species of fire of this description. According to a notice in the *Magazin der Erfindungen* (Magazine of Discoveries), the Baron Von Aretin of Munich has discovered in a Latin MS. of the 13th century, in the central library in that city, a dissertation on the Greek fire, which contains the receipt for its composition, so long supposed to be lost.

Fire-Escape. Among the various expedients for facilitating the escape of persons in danger from fire, one of the earliest appears to have been the employment of ladders. But, unfortunately, it too often happens, that when they are wanted, nobody remembers where they are, or will take the trouble to fetch them.

About the year 1810, Mr. Davis invented a very excellent machine on the ladder principle, for which he was deservedly rewarded by the Society of Arts with a donation of 50 guineas. It consisted of three ladders, of moderate length, sliding into each other, and supported perpendicularly on a low carriage with four wheels. By the mechanical arrangements of the machine, these ladders were capable of being inclined at any required angle, and projected with great facility one above the other, so as to form a single ladder, of sufficient length to reach the upper windows of ordinary houses. For the greater security of persons descending the ladders, they were furnished with hand-rails on each side, and at the upper extremity of the machine a pulley and ropes were fixed, by which either persons or goods might be lowered in a basket. Another advantage connected with this apparatus was, that it would enable the firemen to elevate the engine-hose, and direct the branch *horizontally* at any required height by means of guide-ropes, so that the whole force of the stream might be brought to bear upon the flames in an upper apartment, instead of the mere force of descent which the water exerts, under ordinary circumstances, by its fall from the apex of the parabolic curve described by the jet.

Several improvements were subsequently made on this invention by Mr. Gregory, and it was still farther simplified by Mr. Hudson, the philanthropic projector of the Society for Preventing the Loss of Life by Fire.

Mr. Doyle has adapted a series of intersecting levers to the construction of a fire-escape. The principle upon which this machine is constructed, is identical with that of an instrument known by the name of the *lazy tongs*. The instrument consists of a combination of levers of the first kind, crossing each other like the two sides of a pair of scissors, and moving on joints at their extremities and at the points of intersection. The effect of this arrangement is, that when the handles or lower arms of the system of levers are fully extended, the instrument is contracted into a very small compass, but is extended to a considerable length when the handles are brought together. In Mr. Doyle's fire-escape two such instruments as we have described were connected by transverse bars, so as to form a kind of open frame-work, which supported a railed platform. The whole apparatus may be placed on a small carriage, but by simply turning a handle, the platform can in a moment be projected to an altitude of about forty feet.

A fire-escape of a very simple construction has been suggested by Mr. Charles M. Willich, to the Society of Arts. The idea is not new, as blankets have been often used with success; but if the plan pointed out by Mr. W. were adopted, and a system established, many lives might be saved. It consists of a horse-hair net, about 14 feet long, by 8 wide. He recommended that every police station should be furnished with one, which on an alarm of fire should be immediately brought to the spot. The manner of using the net is self-evident. There are always a sufficient number of persons present, who would hold it extended. Horse-hair is recommended, on account of its durability and elasticity. A fire-escape must be *always* perfect, and at hand speedily, or it is useless.

FIRE-PLACE. We often see old fire-places of an enormous size, capable of containing seats, and having the sides at right angles with the back, which is perpendicular. This construction was attended with very great loss of heat, as the size of the mouth occasioned a great current of air up the chimney, and, consequently, into the room; and almost all the radiated and conducted heat was carried off. The application of modern practical science to the comfort of common life has been of the greatest benefit in this respect. Wood is still the principal fuel in the United States; but coal is in some districts now coming into general use. The arrangement need not be essentially different whichever kind of fuel is employed. It is advantageous to make the perpendicular height of the fuel as great as is consistent with safety. A stratum of coals, or ignited wood, will radiate more heat into the lower part of the room, if placed vertically, than if laid horizontally. The fuel should also be so divided as to be easy of ignition, and so placed as to give free access of the air to all its parts, as the smoke is then more likely to be burnt.

Franklin's stoves are cast-iron fire-places, and, when executed according to the inventor's directions, are a very economical contrivance. Most of the articles, however, now sold under this name, are very different from the original plan. Underneath and behind the fire-place is an air chamber, into which the air is admitted from without the house, by an opening through the wall, and which is discharged into the apartment by lateral openings, after being heated by contact with the fire-place. The smoke, being carried off by a circuitous flue, which passes upwards to the top of the fire-place, and then descends to the floor, also parts with much of its heat before it escapes by the main chimney.

The *Rumford fire-place* is a common fire-place, constructed with a narrow throat to the chimney, for the purpose of diminishing the current of air, an advanced back to throw the fire farther forward, and oblique sides (at an angle of about 135 degrees with the back), which radiate the heat more completely into the room.

The *double fire-place* is an ingenious modification of a Franklin stove. It is formed by setting a small stone fire-place into the chimney, leaving an air chamber, as in the Franklin stove, behind and beneath it, which communicates with the external air, and opens into the apartment. This fire-place is so constructed, as to unite the advantages of the Rumford fire-place with those of a Franklin stove. The air to be heated should be taken from without the house; for if taken from an entry or cellar, the temperature of those places would be very much reduced. The air chamber should be from four to seven inches in diameter, as more heat will be conducted from the stone, and a great quantity of air moderately heated is better than a small quantity made very hot, which is apt to render the air of the apartment disagreeable. (See GRATE, STOVE, and FURNACE.)

FIRE-SHIPS are generally old vessels filled with combustibles fitted with grappling-irons, to hook enemies' ships and set them on fire. The following is a description of the fire-ships which were of such essential service to the Greeks in their late struggle with Turkey: "The vessels usually employed for this service," says Mr. Emerson, "are old ships purchased by the government.

"Their construction, as fire-ships, is very simple; nothing more being wanted than active combustion. For this purpose the ribs, hold, and sides of the vessel, after being well tarred, are lined with dried furze, dipped in pitch and lees of oil, and sprinkled with sulphur; a number of hatchways are then cut along the deck, and under each is placed a small barrel of gunpowder; so that at the moment of conflagration, each throws off its respective hatch, and, giving ample vent to the flames, prevents the deck being too soon destroyed by the explosion. A train which passes through every part of the ship, and communicates with every barrel, running round the deck, and passing out at the steerage window, completes the preparation below; whilst above, every rope and yard is well covered with tar, so as speedily to convey the flames to the sails; and at the extremity of each yardarm is attached a wickered hook, which, being once entangled with the enemy's rigging, renders escape, after coming in contact, almost a matter of impossibility.

The train, to prevent accidents, is never laid till the moment of using it; when, all being placed in order, and the wind favourable, with every possible sail set, so as to increase the flames, she bears down upon the enemy's line, whilst the crew, usually twenty-five or thirty in number, have no other defence than crouching behind the after bulwarks. When close upon the destined ship, all hands descend by the stern into a launch fitted out for the purpose, with high gunwales and a pair of small swivels; and at the moment of contact, the train is fired by the captain, and every hatch being thrown off, the flames burst

forth at the same instant from stem to stern; and, ascending by the tarred ropes and sails, soon communicate with the rigging of the enemy's vessel, who have never yet in one instance been able to extricate themselves. In fact, such was the terror with which they inspired the Turks, that they seldom made the slightest resistance. On the distant approach of the fire-ship, they maintain for some moments, an incessant random cannonade; but at length, long before she comes in contact, precipitate themselves into the sea, and attempt to reach the other vessels, scarcely one remaining to the last moment to attempt to save the devoted ship.

"Sometimes, however, armed boats are sent off from the other vessels of the fleet; but they have never yet been able, either to prevent the approach of the fire-ship, or seize on the crew whilst making their escape; and, though fire-ships are in other countries considered a forlorn hope, such is the stupidity and terror of the Turks, that it is rarely that one of the brulottiers is wounded, and very seldom indeed that any lose their lives. The service, however, from the risk to which it is exposed, is rewarded with higher pay than the ordinary seamen; and, on every occasion of their success, each brulottier receives an additional premium of 100 or 150 piasters."

Fire-Works. See Pyrotechny.

Firkin, in *commerce;* a measure containing eight gallons of ale, and nine of beer.

Firlot, in *commerce;* a dry measure used in Scotland.

Firmament, in the Ptolemaic astronomy; the eighth heaven or sphere, with respect to the seven spheres of the planets which it surrounds. It is supposed to have two motions, a diurnal motion, given to it by the *primum mobile,* from east to west, about the poles of the ecliptic; and another opposite motion, from west to east, which last it finishes, according to Tycho, in 25,412 years; according to Ptolemy, in 36,000; and according to Copernicus, in 25,800; in which time the fixed stars return to the same points in which they were at the beginning. This period is commonly called the *Platonic year,* or the *great year.*

Fishery; a place where great numbers of fish are caught. The principal fisheries for salmon, herring, mackarel, pilchards, &c., are along the coast of England, Scotland, and Ireland; for cod, on the banks of Newfoundland; for whales, about Greenland; and for pearls, in the East and West Indies.

Fishery denotes also the commerce of fish, more particularly the catching them for sale. Were we to enter into a very minute and particular consideration of fisheries, as at present established in this kingdom, this article would swell beyond its proper bounds; because to do justice to a subject of that concernment to the British nation, requires a very ample and distinct discussion. We shall, however, observe, that since the coasts of Great Britain and Ireland abound with the most valuable fish; and since fisheries, if successful, become permanent nurseries for rearing expert seamen; it is a duty we owe to our country, for its natural security, to extend this trade to the utmost. No nation can have a navy, where there is not a fund of business to breed and employ seamen, without any expense to the public, and no trade is so well calculated for training up these useful members of society, as fisheries.

The situation of the British coast is the most advantageous for catching fish in the world; the Scottish islands, particularly those to the north and west, lie most commodious for carrying on the fishing trade to perfection: for no country in Europe can pretend to compete with Scotland in the abundant supply of the finest fish, with which its various creeks, bays, rivers, lakes, and coasts are replenished. King Charles I. was so sensible of the great advantage to be derived from fisheries, that he began the experiment, together with a company of merchants; but the civil war soon occasioned that project to be set aside. King Charles II. made a like attempt, but his pressing wants made him withdraw what money he had employed in the establishment of the fisheries, and the merchants that joined with him did the same. Since the Union, several attempts have been made to retrieve the fisheries, and a corporation was formed for that purpose, entitled the Royal British Fishery.

In the year 1750, the Parliament of Great Britain taking the state of the fisheries into consideration, an act was passed for the encouragement of the white herring fishery, also granting a charter, whereby a corporation was created, to continue 21 years, by the name of the Society of the Free British Fishery, to be under the direction of a governor, president, vice-president, council, &c., who were to continue in office the space of three years, with power to make by-laws, &c., and to raise a capital of 500,000*l.* by way of subscription. And "any number of persons, who, in any part of Great Britain, shall subscribe 10,000*l.* into the stock of this society, under the name of the Fishing Chamber, and carry on the said fishery on their own account of profit and loss, shall be entitled to the same bounty allowed to the society." The bounty is 30*s.* the tun, to be paid yearly, for fourteen years, besides three per cent. for the money advanced by each chamber. The act contains other proper regulations relative to the nets, marks on the herring-barrels, number of hands, the quantity of salt that is entitled to the bounty, &c. It is then by the encouragement originally given by this act, that we see a laudable emulation prevailing all over the kingdom, and fishing vessels fitted out from almost every part, in order to repair to the Shetland Islands, where the herring fishery is carried on with an ardour becoming so important a branch of trade. Scotland, which suffered incredibly from the neglect of this valuable and natural produce of the seas, has not been backward to join in a scheme that tends so evidently to its own advantage; for the cities of Edinburgh and Glasgow, the towns of Montrose, Dundee, Perth, Inverness, and some other boroughs, have raised the proper sum, and chambers have been erected in each of them; the gentlemen of landed property adjoining to the respective places above mentioned, liberally contributing with the merchants towards the prosecution of an undertaking so visibly tending to the good of their country in general.

Fishery, cod. There are two kinds of cod fish, the one green or white cod, the other dried or cured cod, though it is all the same fish differently prepared; the former being sometimes salted and barrelled, then taken out for use; and the latter having laid some considerable time in salt, dried in the sun or smoke. We shall therefore speak of each of these separately.

Fishery, green cod. The chief fisheries for green

cod are in the bay of Canada, on the great bank of Newfoundland, and on the Isle of St. Peter, and the Isle of Sabel, to which places vessels resort from different parts, both of Europe and America. They are from 100 to 150 tons burthen, and will catch between thirty and forty thousand cod each. The most essential part of the fishery, is to have a master who is skilful in cutting up the fish, and above all a good salter, on which the preserving them, and consequently the success of the voyage, depends. The best season is from the beginning of February to the end of April; the fish, which in the winter retire to the deepest water, coming then on the banks, and are then easily taken. What are caught from March to June keep well, but those taken in July, August, and September, when it is warm on the banks, are apt to spoil soon. Every fisher takes but one at a time; the most expert will take from 350 to 400 in a day, but that is the most, the weight of the fish, and the great coldness of the air, on the bank very much fatiguing the men. As soon as the cod are caught, the head is taken off; they are opened, and the intestines withdrawn; the salter then stows them in the bottom of the hold, head to tail, in beds; laying layers of salt and fish alternately, but never mixing fish caught on different days. When they have lain thus three or four days to drain off the water, they are replaced in another part of the ship, and salted again; where they remain till the vessel is loaded. Sometimes they are cut in thick pieces, and put up in barrels for the convenience of carriage.

Fishery, dry cod. The principal fishery for dry cod is from Cape Rose to the Bay des Exports, along the coast of Placentia, there being many convenient inlets or small ports for the fish to be dried in. These, though of the same kind with the fresh cod, are much smaller, and therefore fitter to keep, as the salt penetrates more easily into them. The fishery of both is much alike, only this latter is more expensive, as it takes up more time, and employs more hands, and yet scarce half as much salt is spent in this as in the other. The bait is herrings, of which great quantities are taken on the coast of Placentia. When several vessels meet, and intend to fish in the same part, he whose shallop first touches ground, becomes entitled to the quality and privileges of admiral; he has the choice of his station, and the refusal of all the wood on the coast at his arrival. As fast as the masters arrive, they unrig all their vessels, leaving nothing but the shrouds to sustain the masts, and in the mean time the mates provide a tent on shore, covered with branches of trees, and sails over them, with a scaffold of great trunks of pines, twelve, fifteen, sixteen, and often twenty feet high, commonly from forty to sixty feet long, and about one-third as much in breadth. While the scaffold is preparing, the crew are fishing, and as fast as they catch they bring their fish on shore; open and salt them upon moveable benches, but the main salting is performed on the scaffold. When the fish have taken salt, they wash and hang them to drain on rails; when drained, they are laid on stages, which are small pieces of wood laid across, and covered with branches of trees, having the leaves stripped off for the passage of the air. On these stages they are disposed, head against tail, with the back uppermost, and are turned carefully four times every twenty-four hours. When they begin to dry, they are laid in heaps ten or twelve thick, in order to retain their warmth; and every day the heaps are enlarged, till they become double their original bulk; when two heaps are joined together, which they turn every day as before; lastly, they are salted again, beginning with those first salted, and being laid in huge piles, they remain in that situation till they are carried on board the ship, where they are laid on the branches of trees disposed for that purpose, upon the ballast, and round the ship, with mats to prevent their contracting any moisture. There are four distinct articles of commerce drawn from cod, viz., the zounds, the tongues, the roes, and the oil extracted from the liver. The first is salted at the fishery, together with the fish, and put up in barrels of from 600 to 700 lbs. The tongues are prepared in a similar manner, and brought in barrels containing from 400 to 500 lbs. The roes are also salted in barrels, and serve to cast into the sea to draw fish together, and particularly pilchards. The oil comes in barrels of from 400 to 520 lbs. and is used in dressing leather. The Scotch catch a small kind of cod on the coast of Buchan, and all along the Murray Firth on both sides; as also in the Firth of Forth, Clyde, &c., which is much esteemed. They salt and dry them in the sun upon rocks, and sometimes in the chimney. They also cure skait, and other smaller fish in the same manner, but most of these are for home consumption.

Fishery, herring. Herrings are chiefly found in the North Sea. They are a fish of passage, and commonly go in shoals, being very fond of following fire or light. About the beginning of June, an incredible shoal of herrings, probably much larger than the land of Great Britian and Ireland, come from the north on the surface of the sea; their approach is known by the hovering of sea-fowl in expectation of prey, and by the smoothness of the water; but where they breed, or what particular place they come from, cannot be easily discovered. As this great shoal passes between the shores of Greenland and the North Cape, it is probably confined, and as it reaches the shores of Great Britain, is necessarily divided into two parts. For we find one part of the herrings steering west, or south-west, and leaving the islands of Shetland and Orkney to the left, pass on towards Ireland, where being interrupted a second time, some keeping the shore of Britain, pass away south, down St. George's Channel; while the other part, edging off to the south-west, coast the Western Ocean, till they reach the south shore of Ireland, and then steering south-east, join the rest in St. George's Channel. The other part of the first division made in the north, parting a little to the east and south-east, pass by Shetland, and then make the point of Buchanness, and the coast of Aberdeen, filling as they go all the bays, firths, creeks, &c., with their innumerable multitudes. Hence they proceed forward, pass by Dunbar, and rounding the high shores of St. Abb's Head and Berwick, are seen again off Scarborough; and even then not diminished in bulk, till they come to Yarmouth Roads, and from thence to the mouth of the Thames, after which, passing down the British Channel, they seem to be lost in the Western Ocean.

The vast advantage of this fishery to this country is obvious, when we consider that, though herrings are found upon the shores of North America, they are never seen there in such quantities as with us, and that they are not to be met with in considerable numbers in any of the southern kingdoms of Europe,

as Spain, Portugal, or the southern parts of France; on the side of the ocean, or in the Mediterranean, or on the coast of Africa. There are two seasons for fishing herring, the first from June to the end of August, and the second in autumn, when the fogs become very favourable to this kind of fishing. There is nothing particular in the manner of fishing. The nets in which the fish are drawn should regularly have their meshes an inch square, to let all the lesser fry go through.

The commerce in herrings, white or pickled, and red, is very considerable. The white Dutch herrings are the most esteemed, being distinguished into four sorts, according to their sizes; and the best are those that are fat, fleshy, firm, and white, salted the same day they are taken with good salt, and well barrelled. The British herrings are little inferior, if not equal to the Dutch; for, in spite of all their endeavours to conceal the secret, their method of curing, "lasting," or casking the herrings, is now well known.

Fishery, mackarel. The mackarel are found in large shoals in the ocean, but especially on the French and English coasts. They enter the English channel in April, and proceeding as the summer advances, about June they are on the coast of Cornwall, Sussex, Normandy, Picardy, &c., where the fishery is most considerable. They are taken either with a line or nets: the latter is preferable, and is usually performed in the night time. They are pickled two ways, first by opening and gutting them, and cramming their bellies as hard as possible with salt, by means of a stick, and then laying them in rows at the bottom of the vessel, strewing salt between each layer. The second way is putting them directly into tubs full of brine, made of salt and fresh water, and leaving them to steep till they have taken salt enough to keep. After this, they are barrelled up and pressed close down.

Fishery, pilchard. The chief pilchard fisheries are along the coasts of Dalmatia, on the coast of Bretagne, and along the coasts of Cornwall and Devonshire. That of Dalmatia is very plentiful; that on the coast of Bretagne employs about 300 ships. The pilchards caught on our coasts, though larger, are not so much valued as those on the coast of France, owing principally to their not being so thoroughly cured. They naturally follow the light, which contributes much to the facility of the fishery; the season is from June to September. On the coasts of France they make use of the roes of cod fish, as a bait, which, thrown into the sea, makes them rise from the bottom and run into the nets; on our coasts there are persons posted ashore, who, ascertaining by the colour of the water where the shoals are, make signs to the boats to go among them to cast their nets. When taken, they are brought on shore to a warehouse, where they are laid up in broad piles supported with backs and sides, and as they are piled they salt them with bay salt, in which lying to soak twenty or thirty days, they run out a deal of blood, with dirty pickle and bittern; then they wash them clean in salt-water, and, when dry, barrel and press them hard down to squeeze out the oil, which issues out of a hole in the bottom of the cask. The Cornishmen observe of the pilchard, that it is the least fish in size, most in number and greatest for gain, of any they take out of the sea.

Fishery, salmon. The chief salmon fisheries in Europe are in England, Scotland, and Ireland, in the rivers and sea-coasts adjoining to the mouths of rivers Those most distinguished for salmon in Scotland, are the river Tweed, the Clyde, the Tay, the Dee, the Don, the Spey, the Ness, the Bewley, &c. The chief rivers in England for salmon are the Tyne, the Trent, the Severn, and the Thames. The fishing is not allowed to commence in Scotland before the first of February, and it must be closed by the fourteenth of September. The fishing is performed with nets, and sometimes with movable locks or wears made on purpose, which in certain places have iron or wooden grates so disposed, in an angle, that, being impelled by any force in a contrary direction to the course of of the river, they may give way and open a little at the point of contact, and immediately shut again, closing the angle. The salmon therefore, coming up into the rivers, are admitted into these gates, which open, and suffer them to pass through, but shut again and prevent their return. Salmon are also caught with a spear, which they dart into the fish when they see him swimming near the surface of the water. It is customary likewise, to catch them with a candle and lanthorn, or wisp of straw set on fire; for the fish naturally following the light, are struck with the spear, or taken in a net prepared for that purpose, and lifted with a sudden jerk from the bottom. We make no mention of the method of catching salmon with a line or hook, because it is much the same with trout fishing.

Curing salmon. When the salmon are taken, they open them along, take out the intestines, &c., and cut out the greatest part of the bones, endeavouring to make the inside as smooth as possible, then salt the fish in large tubs for the purpose, where they remain a considerable time soaking in brine, and about October they are packed close in barrels, and sent to London, or exported up the Mediterranean. They have also in Scotland a great deal of salmon salted in the common way, which, after soaking in brine a competent time, is well pressed, and then dried in smoke: this is called kipper, and is chiefly made for home consumption, and, if properly cured and prepared, is reckoned very delicious.

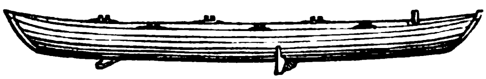
Fishery, sturgeon. The greatest sturgeon fishery is in the mouth of the Volga, on the Caspian Sea, where the Russians employ a great number of hands, and catch them in a kind of inclosure, formed by huge stakes, representing the letter Z, repeated several times. These fisheries are open on the side next the sea, and close on the other, by which means the fish ascending up the river are embarrassed in these narrow angular retreats, and thus are easily killed with a harpoon. Sturgeons, when fresh, eat deliciously; and, in order to make them keep, they are salted or pickled in large pieces, and put up in kegs containing from 30 to 50 pounds. But the great object of this fishery is the roe, of which the Russians are extremely fond, and of which is made the cavia or kavia, so much esteemed by the Italians.

Fishery, whale. Whales are chiefly caught in the North Sea: the largest sort are found about Greenland, or Spitzbergen. At the first discovery of this country, whales not being used to be disturbed, frequently came into the very bays, and were accordingly killed almost close to the shore, so that the blubber being cut off, was immediately boiled into oil on the spot. The ships, in those times, took in nothing but the pure oil and fins, and all the business was executed in the country, by which means, a ship could bring home the product of many more whales

than she can according to the present mode of conducting this trade. The fishery also was then so plentiful, that they were obliged sometimes to send other ships to fetch off the oil they had made, the quantity being more than the fishing ships could bring away. But time and change of circumstances have shifted the situation of this trade. The ships coming in such numbers from Holland, Denmark, Hamburgh, and other northern countries, all intruders upon the English, who were the first discoverers of Greenland, disturbed the whales, and gradually, as other fish often do, forsaking the place, were not to be killed so near the shore as before; but are now generally found in the openings and spaces among the ice, where they have deep water, and where they go sometimes a great many leagues from the shore.

The whale fishery begins in May, and continues all June and July; but, whether the ships have good or bad success, they must come away and get clear of the ice about the close of August, so that in the month of September they may be expected home; but a ship that meets with a fortunate and early fishery in May, may return in June or July.

The manner of taking whales at present is as follows: as soon as the fishermen hear the whale blow, they cry out Fall! fall! and every ship gets out its boat, in each of which there are six or seven men. These boats are peculiarly formed, combining speed with great steadiness. We give an engraving of one employed in the South Seas.



They row till they come pretty near the whale, when the harpooner strikes it with his harpoon. This requires great dexterity, for through the bone of the head there is no striking, but near his snout there is a soft piece of flesh, into which the iron sinks with ease. As soon as he is struck they take care to give him rope enough, otherwise when he goes down, which he frequently does, he would inevitably sink the boat: this rope he draws with such violence, that if it were not well watered, it would, by its friction against the sides of the boat, be soon set on fire. The line fastened to the harpoon is many fathoms long, and is called the fore-runner: it is made of the finest and softest hemp, that it may slip the easier; to this they join a heap of lines of 90 or 100 fathoms each, and when there are not enough in one long boat, they borrow from another. The man at the helm observes which way the rope goes, and steers the boat accordingly, that it may run exactly out before; for the whales run away with the line with such rapidity, that it would overset the boat if it were not kept straight. When the whale is struck, another long boat rows before and observes which way the line stands, and sometimes pull it; if they feel it stiff, it is a sign the whale still pulls in strength, but if it hangs loose, and the boat lies equally high behind and before upon the water, they pull it in gently, but take care to coil it so that the whale may have it again easily if he recovers strength. They are careful, however, not to give him too much line, because he sometimes entangles it about a rock, and pulls out the harpoon. The fat whales do not sink as soon as dead, but the lean ones do, and come up some days afterwards. As long as they see whales they lose no time in cutting up what they have taken, but keep fishing for others; when they see no more, or have taken enough, they begin with taking off the fat in the following manner: the whale being lashed alongside, they lay it on one side, and put two ropes, one at the head, and the other in the place of the tail, which, together with the fins, is struck off as soon as he is taken, to keep those extremities above water. On the off side of the whale are two boats to receive the pieces of fat, utensils, and men, that might otherwise fall into the water on that side. These precautions being taken, three or four men, with irons at their feet to prevent slipping, get on the whale, and begin to cut out pieces of about three feet thick and eight long, which are hauled up at the capstan or windlass. When the fat is all got off, they cut off the whiskers of the upper jaw with an axe. Before they are cut they are all lashed to keep them firm, which also facilitates the cutting, and prevents them from falling into the sea; when on board, five or six of them are bundled together and properly stowed, and after all is got off, the carcase is turned adrift, and devoured by the bears and sharks, who are very fond of it. In proportion as the large pieces of fat are cut off, the rest of the crew are employed in slicing them smaller, and picking out all the lean. When this is prepared, they stow it under the deck, where it lies till the fat of all the whales is on board; then, cutting it still smaller, they put it up in tubs in the hold, squeezing them very close. Nothing now remains but to sail homewards, where the fat is to be boiled and melted down into train oil. In some cases, however, the boiling is done on the spot.

It is unnecessary to speak in this place of the advantages that are derived to Great Britain from the whale fishery.

Besides these fisheries, there are several others both on the coast of Great Britain and in the North Seas, which although not much the subject of merchandize, nevertheless employ great numbers both of ships and men; as 1. The oyster fishery at Colchester, Feversham, the Isle of Wight, in the Swales of the Medway, and in all the creeks between Southampton and Chichester, from whence they are carried to be fed in pits at Wevenloe, and also to many other places.

2. The lobsters are caught along the British Channel, the Firth of Edinburgh, on the coast of Northumberland, and on the coast of Norway, from whence great quantities are brought to London. The fishing for the pot-fish, fin-fish, sea-unicorn, sea-horse, and the seal, or dog-fish, are very valuable to this country; besides which it may be especially noticed, that the horn of the sea-unicorn is as estimable as ivory, and the skins of the seals are particularly useful in various branches of commerce.

Fitchee, in *heraldry*; an epithet for a cross that ends in a sharp point. It is supposed to have taken its rise from the practice of Christians formerly carrying the cross with them wherever they went, which they fixed in the ground as they stopped.

Fixation, in *alchemy*; the making any volatile spirituous body endure the fire, and not fly away either by repeated distillations or sublimations.

Fixed Air; a name formerly applied to carbonic acid gas.

Fixed Oils. There are two species of oil in vegetables, agreeing in the common properties of unctuosity and inflammability, but essentially differ-

ent in many of their chemical qualities. The one being capable of being volatilized without decomposition, is named *volatile oil*, the other is denominated *fixed oil*. The latter is generally contained in the seeds and fruits of vegetables, and varies in its properties, according to the plants by which it is afforded. The fixed oils are extracted by pressure, and accordingly are frequently called *expressed oils*. When the process is aided by heat, the action of which is to render the oil more fluid, the product is esteemed less pure. The purest oils are those expressed from the fruit of the olive, or the seeds of the almond; others, less pure, come from flax-seed and hemp-seed. These oils are usually fluid, but of a somewhat thick consistence, and liable to congeal at very moderate colds; palm-oil is even naturally concrete. When fluid, they are transparent, of a yellow or yellowish green colour, and capable of being rendered quite transparent by the use of animal charcoal. They are inodorous and insipid, at least if they have been obtained with due care; and free from the mucilaginous and extractive matter of the plants from whence they come; are lighter than water, with which they do not unite, and are very sparingly soluble in alcohol, with the exception of castor-oil.

At a temperature below 600° Fahrenheit, they remain unchanged. In the neighbourhood of this temperature, however, they begin to boil, and to disengage an inflammable vapour; but the oil thus condensed is altered in its properties; it loses its mildness, becomes more limpid and volatile, a portion of carbon being likewise deposited. Transmitted through an ignited tube, fixed oil is converted into carbonic acid and carbureted hydrogen, with a small portion of acid liquor, and a residuum of charcoal. In the open air, it burns with a clear white light, and formation of water and carbonic acid gas. Accordingly, the fixed oils are capable of being employed for the purposes of artificial illumination, as well in lamps as for the manufacture of gas. Fixed oils undergo considerable change by exposure to the air. The rancidity which then takes place is occasioned by the mucilaginous matters which they contain becoming acid. From the operation of the same cause, they gradually lose their limpidity, and some of them, which are hence called *drying oils*, become so dry, that they no longer feel unctuous to the touch, nor give a stain to paper. This property, for which linseed-oil is remarkable, may be communicated quickly, by heating the oil in an open vessel. The drying oils are employed for making oil-paint, and, mixed with lamp-black, constitute printers' ink. During the process of drying, oxygen is absorbed in considerable quantity. This absorption of oxygen is, under certain circumstances, so abundant and rapid, and accompanied with such a free disengagement of caloric, that light, porous, combustible materials, such as lamp-black, hemp or cotton-seed may be kindled by it. Many instances of spontaneous combustion have occurred from this cause; and particularly in the Russian arsenals, where, at length, a series of experiments was instituted to ascertain the accompanying circumstances. It appears from these investigations, that if hemp, flax, or linen cloth, steeped in linseed oil, lie in a heap, and be somewhat pressed together and confined, its temperature rises, a smoke issues from it, and, at length, sometimes within twenty four or even twelve hours, it takes fire. The same thing happens with mixtures of oil and fine charcoal, and with lamp-black wrapped up in linen; from whence it is conjectured, that many extensive fires, which have broken out in cotton manufactories, and for which no cause could be assigned, must have arisen from this spontaneous inflammability of oils.

Fixed oils unite with the common metallic oxides. Of these compounds, the most interesting is that with the oxide of lead. When linseed-oil is heated with a small quantity of litharge, a liquid results which is powerfully drying, and is employed as oil varnish. Olive-oil, combined with half its weight of litharge, forms the common *diachylon plaster*. The fixed oils are readily attacked by alkalies. With ammonia, they form a soapy liquid, to which the name of *volatile liniment* is applied. They are oxidated by a number of the acids. Sulphuric acid soon renders them black; the oxygen of the acid attracting part of the hydrogen of the oil, and causing the deposition of charcoal; and if heat is applied, a large portion of sulphurous acid is disengaged, and even sulphur is evolved. Nitric acid renders them thick; if heat is applied, the action is more rapid, and a yellow colour is communicated, the oil being rendered concrete. Chlorine thickens oil, and renders it white. When boiled in sulphur, a compound is formed of a brown colour, a very fetid smell, and acrid taste. It likewise, when heated, dissolves phosphorus, forming a liquid which becomes luminous when exposed to the air. Olive-oil, according to the analysis of Gay-Lussac and Thénard, consists of carbon 77.213, oxygen 9.427, and hydrogen 13.360.

FIXED STARS; those stars which appear to remain always at the same distance from each other, and in the same relative position. The name comprehends, therefore, all the heavenly bodies, with the exception of the planets, with their moons and the comets. But, besides the apparent motion of the fixed stars, resulting from the diurnal rotation of our earth upon its axis, and from the precession of the equinoxes, and the aberration of light, a very slow proper motion has been observed in them, so that it is not strictly true that the fixed stars remain in the same relative position. It has been found that Sirius, for example, has, since the time of Tycho-Brahe, moved about two minutes from its place, &c. But Herschel (On the Proper Motion of the Sun and Solar System, in the *Philosophical Transactions*, vol. 73.) has proved that this apparent change of place results from a real motion of our whole solar system in the celestial spaces. Stars have also been seen to appear suddenly in the heavens, and again to disappear. Of others it has been remarked that their size appears alternately to increase and to diminish. Their distance from our earth is, in the most literal sense of the word, immeasurable. The most powerful telescopes cannot give them a sensible diameter.

We can obtain an idea of their size from the circumstance that, although we approach them by forty millions of miles (the diameter of the earth's orbit), and recede from them as far, we can find no difference in them. Huygens, by comparing the light of Sirius with that of the sum, tried to determine its distance from the earth, and upon the supposition that Sirius is of the same size as the sun, made its distance 27,664 times greater. However conjectural such determinations must be, they entirely succeed in proving to us that the celestial spaces have an extent beyond the power of the human mind to con-

ceive. We are in equal uncertainty with regard to the nature and constitution of the fixed stars; but it is in the highest degree probable that they are luminous worlds or suns, around which, as around our sun, planets revolve in determined paths, receiving from them light and heat.

The fixed stars are divided according to the difference in their brilliancy, which are very visible to the naked eye, into stars of the first, second, third magnitude, &c. But besides these stars, which appear in the heavens as distinct bright points of light, the eye, in the clear winter nights, sees here and there little white clouds. These nebulous spots are groups of innumerable stars, which the telescope reveals to us; and the limited power of our instruments alone prevents us from looking forward without end, into the infinite regions of space.

Much general information is to be found in *Bode's Introduction to a Knowledge of the Starry Heavens*, (19th edition, Berlin, 1823). In order to distinguish more easily the fixed stars from each other, names were given to the most remarkable of them in very ancient times, and they were divided into groups or constellations. Astronomers have given descriptions of all the stars, according to their situations, with their names, magnitude, &c. Cassini, Lalande, Zach, and Piazzi have done so; and great praise is due to J. E. Bode's *Uranographia, sive Astrorum Descriptio, xx tabulis æneis incisa, ex recentissimis et absolutissimis Astrorum Observationibus.*

FLAG; an ensign or colours, a cloth on which are usually painted or wrought certain figures, and borne on a staff;—in the army, a banner by which one regiment is distinguished from another;—in the marine, a certain banner by which an admiral is distinguished at sea from the inferior ships of his squadron; also the colours by which one nation is distinguished from another. In the British navy, flags are either red, white, or blue, and are displayed from the top of the main-mast, fore-mast or mizzen-mast, according to the rank of the admiral. When the flag is displayed at the main-top-gallant-mast head, the officer distinguished thereby is known to be an admiral; when from the fore-top-gallant-mast head, a vice-admiral; and when from the mizzen-top-gallant-mast head, a rear-admiral.

The union is the highest admiral's flag. The next flag after the union is white, at the main; and the last, which characterizes an admiral, is blue, at the same mast-head. For a vice-admiral, the first flag is red, the second white, and the third blue, at the fore-top-gallant-mast head. The same order is observed with regard to rear-admirals, whose flags are displayed at the mizzen-top-gallant-mast head. The lowest flag in this navy is, accordingly, blue at the mizzen.

All the white flags have a red St. George's cross in them, inserted originally, to distinguish them from the old French white flag with a white cross. The French national flag, since the late revolution, is the tri-coloured flag, red, white, and blue. When a council of war is held at sea, if it be on board the admiral, they hang a flag on the main shrouds; if in the vice-admiral, in the fore shrouds; and if in the rear-admiral, in the mizzen shrouds. The flags borne on the mizzen are particularly called *gallants.*

To heave out the flag, is to put out or hang abroad the flag. To hang out the white flag, is to call for quarter; or it shows, when a vessel arrives on a coast, that it has no hostile intention, but comes to trade or the like. To hang out the red flag, is to give a signal of defiance and battle. To lower or strike the flag, is to pull it down upon the cap, or to take it in, out of the respect or submission due from all ships or fleets, to those any way justly their superiors. To lower or strike the flag, in an engagement, is a sign of yielding. The way to lead a ship in triumph is, to tie the flags to the shrouds, or the gallery in the hind-part of the ship, and let them hang down towards the water, and tow the vessel by the stern. Livy relates that this was the way the Romans used the vessels of Carthage. (See STANDARDS.)

FLAGEOLET; a small pipe or flute, the notes of which are exceedingly clear and shrill. It is generally made of box or other hard wood, though sometimes of ivory, and has six holes for the regulation of its sounds, besides those at the bottom and mouth-piece, and that behind the neck.

FLAIL; an instrument for thrashing corn, that consists of—1. the hand-staff, which the labourer holds in his hand; 2. the swiple, or that part which strikes the corn; 3. the caplins, or leathern thongs that bind the hand-staff and swiple; 4. the middle band, being the leathern thong, or fish-skin, that ties the caplins together.

FLAMBEAU; a kind of large taper, made of hempen wicks, by pouring melted wax on their top, and letting it run down to the bottom. This done, lay them to dry, after which roll them on a table, and join four of them together by means of a red-hot iron; and then pour on more wax, till the flambeau is brought to the size required. Flambeaus are of different lengths, and made either of white or yellow wax. They serve to give light in the streets at night, or on occasion of illuminations.

FLAME. Newton and others have considered flame as an ignited vapour, or red-hot smoke. This, in a certain sense, may be true; but, no doubt, it contains an inaccurate comparison. It appears to be well ascertained, that flame always consists of volatile inflammable matter, in the act of combustion, or combination with the oxygen of the atmosphere. Many metallic substances are volatilized by heat, and burn with a flame, by the contact of the air in this rare state. Sulphur, phosphorus, and some other basis of acids, exhibit the same phenomenon. But the flames of organized substances are in general produced by the extrication and ascension of hydrogen gas, with more or less of charcoal.

When the circumstances are not favourable to the perfect combustion of these products, a portion of the coal passes through the luminous current unburned, and forms smoke. Soot is the condensed matter of smoke. As the artificial light of lamps and candles is afforded by the flame they exhibit, it seems a matter of considerable importance to society, to ascertain how the most luminous flame may be produced with the least consumption of combustible matter.

There does not appear to be any danger of error in concluding, that the light emitted will be greatest when the matter is completely consumed in the shortest time. It is therefore necessary that a stream of volatilized combustible matter, of a proper figure, at a very elevated temperature, should pass into the atmosphere with a certain determinate velocity. If the figure of this stream should not be duly proportioned—that is to say, if it be too thick—its in-

ternal parts will not be completely burned, for want of contact with the air. If its temperature be below that of ignition, it will not burn when it comes into the open air. And there is a certain velocity, at which the quantity of atmospherical air which comes in contact with the vapour will be neither too great nor too small; for too much air will diminish the temperature of the stream of combustible matter so much as very considerably to impede the desired effect; and too little will render the combustion languid.

We have an example of a flame too large, in the mouths of the chimneys of furnaces, where the luminous part is merely superficial, or of the thickness of about an inch or two, according to circumstances, and the internal part, though hot, will not set fire to paper passed into it through an iron tube; the same defect of air preventing the combustion of the paper as prevented the interior fluid itself from burning. And in the lamp of Argand, we see the advantage of an internal current of air, which renders the combustion perfect by the application of air on both sides of a thin flame. So likewise a small flame is whiter and more luminous than a larger; and a short snuff of a candle, giving out less combustible matter in proportion to the circumambient air, the quantity of light becomes increased to eight or ten times what a long snuff would have afforded. (See CALORIC and COMBUSTION.)

FLANCH, in *heraldry;* one of the honourable ordinaries formed by an arch line, which begins at the corners of the chiefs and ends in the base of the escutcheon.

FLANK, in *fortification;* that part of a work which affords a lateral defence to another. In a bastion, the flanks are those lines which join the central wall.

In tactics, *flank* signifies the outer extremity of the wing of an army; and it is one of the most common manœuvres to surround this most vulnerable point. The enemy, if proper precautions have not been taken, is then obliged to withdraw his flank; therefore to change his front, and is thus exposed to a defeat. This manœuvre is called *outflanking.* A bold, but not always practicable manœuvre, to prevent the consequences of this attempt, is that of outflanking the enemy who makes it.

FLANNEL; a woollen fabric of great importance in our commerce. Flannel is composed of a woof and warp, and woven after the manner of baise. Various theories have been adopted to prove the utility of flannel as an article of dress: it is unquestionably a bad conductor of heat, and on that account very useful in cold weather; this is accounted for from the structure of the stuff; the fibres touch each other very slightly, so that the heated air moves very slowly through the interstices, which being already filled with air, give little assistance in carrying off the heat. On this subject Count Rumford has made many experiments, from which it should seem, that though linen, from the apparent ease with which it receives dampness from the atmosphere, appears to have a much greater attraction for water than any other, yet that those bodies which receive water in its unelastic form with the greatest ease, or are most easily wet, are not those which in all cases attract the moisture of the atmosphere with the greatest avidity. "Perhaps," says he, "the apparent dampness of linen to the touch arises more from the ease with which that substance parts with the water it contains, than from the quantity of water it actually holds; in the same manner as a body appears hot to the touch in consequence of its parting freely with its heat, while another body, which is really at the same temperature, but which withholds its heat with great obstinacy, affects the sense of feeling much less violently. It is well known that woollen clothes, such as flannels, &c., worn next the skin, greatly promote insensible perspiration. May not this arise principally from the strong attraction which subsists between wool and the watery vapour which is continually issuing from the human body? That it does not depend entirely on the warmth of that covering is clear; for the same degree of warmth produced by wearing more clothing of a different kind does not produce the same effect. The perspiration of the human body being absorbed by a covering of flannel, it is immediately distributed through the whole thickness of that substance, and by that means exposed by a very large surface to be carried off by the atmosphere: and the loss of this watery vapour which the flannel sustains on the one side, by evaporation, being immediately restored from the other, in consequence of the strong attraction between the flannel and this vapour, the pores of the skin are disencumbered, and they are continually surrounded by a dry and salubrious atmosphere." He expresses his surprise, that the custom of wearing flannel next the skin should not have prevailed more universally. He is confident it would prevent a number of diseases; and he thinks there is no greater luxury than the comfortable sensation which arises from wearing it, especially after one is a little accustomed to it. "It is a mistaken notion," says he, "that it is too warm a clothing for summer. I have worn in it the hottest climates, and at all seasons of the year, and never found the least inconvenience from it. It is the warm bath of perspiration confined by a linen shirt, wet with sweat, which renders the summer heats of southern climates so insupportable; but flannel promotes perspiration, and favours its evaporation; and evaporation, as is well known, produces positive cold."

FLASK; a vessel for holding gunpowder, and measuring it out when the piece is to be loaded.

FLASK, or FLASQUE, in *heraldry;* an ordinary which resembles the flanch in form, but is smaller.

FLASQUES, in *gunnery;* the two cheeks of the carriage of a great gun.

FLAX has been cultivated from remote antiquity, throughout a great part of Europe, Asia, and the north of Africa, for various purposes. Its native country is not known with certainty, though, according to Olivier, it is found wild in Persia. This plant is cultivated principally for the fibres yielded by the bark, of which linen cloth is made. The use of this article is so ancient, that no tradition remains of its introduction. The ancient Scandinavians and other barbarous nations were clothed with linen. The mummies of Egypt are enveloped with it, and immense quantities are still made in that country, especially about the mouths of the Nile; and it is worn almost exclusively by the inhabitants. Syria, Barbary, Abyssinia, and other places, are supplied from Egypt. Italy also receives vast quantities from the same country, through the merchants of Constantinople.

The use of linen passed from Egypt into Greece, and afterwards into Italy. Besides forming agree-

able and beautiful apparel, the rags, after being converted into paste, are made into paper. The seeds of the flax are mucilaginous and emollient, and an infusion of them is often used as a drink in various inflammatory disorders: they also yield an oil, which is well known in commerce, and which differs, in some respects, from most expressed oils, as in congealing in water, and not forming a solid soap with fixed alkaline salts. This oil has no remarkable taste, is used for lamps, sometimes in cookery, and also forms the base of all the oily varnish made in imitation of China varnish. It is much employed in the coarser kinds of painting, especially in situations not much exposed to the weather. Equal parts of lime-water and this oil form one of the best applications for burns. The cakes remaining after the oil is expressed, are used for fattening cattle and sheep.

Flax-seed has been substituted for grain in times of scarcity, but it is heavy and unwholesome. In Egypt, flax is sown about the middle of December, and is ripe in March. In Europe and in this country, it is generally sown in the spring, from March to May; sometimes, however, in September and October. In a dry and warm country, it is better to sow in autumn, as the rains of autumn and winter favour its growth, and it acquires strength enough to resist the drought, should there happen to be any in the spring. On the other hand, in cold and moist countries, sowing should be deferred till late in the spring, as too much moisture is hurtful.

A light soil is the most suitable, though good crops are obtained from strong and clayey grounds. As it appears to degenerate when repeatedly sown without changing the seed, it is usual, in some countries, to import the seed from the North of Europe, particularly from Riga, which affords the best. The American seed, also, bears a high reputation, and, in Ireland, is preferred for the lighter soils, and the Baltic for the more clayey. In general, however, in order to prevent its degenerating, it is sufficient to change the soil frequently, by sowing in the heavier lands the seed ripened in the lighter, and the reverse.

There are three varieties of flax: the first produces a tall and slender stem, with very few flowers, ripens late, and affords the longest and finest fibres; the second produces numerous flowers, and is the most proper for cultivation, where the seed is the object; but its fibres are short and coarse; the third is the most common, and is intermediate between the other two. It is important not to mix the seeds of these three varieties, as they ripen at different periods, and, besides, the first should be sown more closely, and the second at greater intervals than the third.

When it is a few inches high, it should be freed from weeds, particularly from the cuscuta, a parasitical plant, consisting of yellowish or reddish filaments, and small white flowers: all the stems which have this plant attached to them should be pulled up and burnt. To prevent its lying on the ground, it is usual, with some, to stretch lines across the field, intersecting each other, and fastened at the intersections. As soon as it begins to turn yellow, and the leaves are falling, it is pulled, tied together in little bundles, and usually left upright on the field till it becomes dry, when the seeds are separated, either by beating on a cloth, or by passing the stems through an iron comb. The stems, after being placed even at the base, are again tied together in bundles for rotting—a process which is necessary to facilitate the separation of the fibres, and which is accomplished in three different manners: 1st. on the earth, which requires a month or six weeks; 2nd. in stagnant waters, which is the most expeditious manner, as only ten days are necessary; but the fibres are of inferior quality; 3rd. in running water, for which about a month is necessary. The finest fibres are produced by this latter mode, and certain rivers are considered as possessing advantages over others. Whatever method be made use of, it is necessary to turn it every three or four days. After this process, it is taken out, dried, and is ready for obtaining the fibres. For this purpose, a handful is taken in one hand, laid upon a table, and beaten with a wooden instrument, afterwards drawn forcibly over the angle of the table with both hands, in order to free it from fragments of the stem. Another method is by machinery. It is afterwards heckled or combed with a sort of iron comb, beginning with the coarser and ending with the finer, and is now ready for spinning.

Mr. Bundy has taken out a patent for breaking and dressing flax and hemp. He constructs a frame carrying three fluted or indented rollers, formed as the frustrums of cones, about seven inches long in the working part, three inches and a half in diameter at the larger end, and two inches at the smaller.

Two of these rollers are placed in proper carriages at the bottom, and the third above, lying upon the two lower ones, but not in immediate contact with them. Springs are so placed as, when occasion requires, to raise the upper roller for the introduction of the flax. A treadle readily enables the operator to bring the rollers in contact, and carry on the process. This operation is continued until all the woody parts become broken and separated from the fibre. When it is intended that the flax should be bleached before it is spun, the patentee adopts the following process:—He constructs trays, in which he places small parcels of the flax, and, after leaving them in cold soft water for a few days, the vegetable is freed of its gluten and colouring matter, when it is to be worked in the machine as already described.

If it is required to be still softer, for spinning into yarn of the best quality, it should be boiled in soap and water, well agitated, and then carefully removed and dried.

Flax, New Zealand. The fibres of this plant are used, by the inhabitants of New Zealand, for cords and clothing, instead of hemp and flax, to which they are much superior. They are, in fact, stronger than any other known vegetable fibres, hardly yielding, in this respect, to silk. The stem of this plant grows six feet high and upwards, is straight, very firm, and is branched or paniculate above, and sheathed at base by the leaves; the leaves are five or six feet long, ensiform, very much compressed at base, where they are disposed on two opposite sides of the stem, and somewhat resemble those of the common cat-tail; the flowers have six petals, six stamens, and one style. In its native country, it grows in both wet and dry places, and is apparently adapted to every kind of soil, but seems to prefer marshy places. The fibres are very long, of a snowy whiteness, and possess the lustre of silk. French enterprize has been awakened to the importance of

introducing the culture of this plant. It bears the climate of the south of France, and has remained in the open air throughout the year. It has succeeded perfectly in Normandy, producing seeds which have been sown, and proved fertile. Every year, as the inner leaves shoot upwards, it loses the outer; and, consequently, the outer leaves should be pulled off when they have acquired their full growth, while the stock may remain in the ground for years. It may be multiplied by off-sets which are separated in the spring. The method by which the New Zealanders obtain the fibres is very tedious; accordingly, the French agriculturists have devised other modes, which promise success.

FLEAM, in *surgery;* an instrument for lancing the gums. Farriers employ an instrument of this name for bleeding horses.

FLEECE, ORDER OF THE GOLDEN, one of the oldest and most honourable orders in Europe, was established by Philip III. of Burgundy, surnamed the Good, January 10, 1430, at Bruges, on the occasion of his marriage with his third wife, Isabella, daughter of King John I. of Portugal. In the beginning of the statutes of the order (1431), Philip says, he took the name from the golden fleece of the Argonaut Jason, and that the protection of the church was the object of the order. He declared himself grand-master, and ordered that this dignity should be hereditary in his successors in the government. The decoration of the order is a chain, composed of flints and steels, alternately; in the middle of which the golden fleece is fastened. Annual chapters were to be held, when the majority was to decide on the admission of new members. But several of the first statutes were changed. Philip himself increased the number of knights from 24 to 31; Charles V. his grandson, to 51. The last chapter was held in 1559, at Ghent. Since that time, the monarch has made knights of the golden fleece according to his pleasure. When, after the death of Charles V. the Burgundian possessions and the Netherlands fell to the Burgundian-Spanish line of the house of Austria, the kings of Spain exercised the office of grand-master of the order; but when Charles III. (Charles VI. in the line of German emperors) received, after the war of the Spanish succession, the Spanish, afterwards the Austrian, Netherlands, he insisted upon being the grand-master of the order. The dispute was not settled, and the order, at present, is conferred both at Vienna and Madrid. The chain is now only the decoration of the grand-master; the other knights wear a golden fleece on a red ribbon. The Spanish golden fleece differs from the Austrian by the inscription *Pretium laborum, non vitæ*, upon the steel. At both courts, the order of the golden fleece is the highest; and, as its nominal object is the protection of religion, it is conferred only on Catholics, Protestant sovereigns making the only exception.

FLEECES, THE ORDER OF THE THREE GOLDEN. August 15th 1809, in the camp at Schönbrunn, Napoleon added a third order to those of the Legion of Honour and of the Iron Crown. It was intended to consist of 100 grand officers, 400 commanders, and 1000 other members, chiefly military men. No civilians, except the grand dignitaries of the empire, ministers who had held their offices ten years, ministers of state after twenty years' service, and presidents of state after three years' service, were to be admitted. Of the military, only those who had received three wounds, in three different battles, were to be admitted. Those regiments which had been present in the great battles of the grand army were to receive this order instead of their eagles; their most meritorious subaltern officers were named commanders, and the most meritorious non-commissioned officer or private of each battalion was to be made a member; the former with an income of 4000 francs, the latter with one of 1000, from the funds of the order. To become a grand officer, it was necessary to have commanded a division of the grand army, in the field or at a siege. The emperor was to be grand-master; the King of Rome was the only hereditary member; the princes of the blood could not be admitted into the order, unless they had served in one campaign, or been at least two years in the army. It is not known what induced the emperor to drop this scheme. The only appointments that were made were those of Count Andreossi, chancellor of the order, and Count Schimmelpenninck, treasurer.

FLEET, in *naval affairs;* a number of ships together in company, or under one commander.

FLESH; the muscles of animals. These consist chiefly of fibrin, with albumen, gelatin, extractive matter, phosphate of soda, phosphate of ammonia, phosphate and carbonate of lime, and sulphate of potash.

FLEXOR, in *anatomy;* an epithet for several muscles whose office it is to bend the parts into which they are inserted, as *flexor carpi radialis*, a muscle of the wrist; *flexor tertii internodii*, a muscle of the thumb; *flexor pollicis brevis*, a muscle of the great toe, &c.

FLINT; a mineral which occurs of all colours, but generally yellowish and dark gray, commonly in a compact amorphous body, rarely crystallized. It is widely spread throughout the earth, in primitive, secondary, and alluvial formations, but especially in limestone. Its principal use is for gun-flints, and it is also reduced to a powder and used in the manufacture of porcelain and glass. This important application of silex will be fully discussed under the latter article. The manufacture of gun-flints is exceedingly simple, and a good workman will make 1000 flints a day. The whole art consists in striking the stone repeatedly with a kind of mallet, and bringing off, at each stroke, a splinter sharp at one end and thicker at the other. The splinters are afterwards shaped at pleasure, by laying the line at which it is wished they should break upon a sharp instrument, and then giving it small blows with a mallet. Large manufactures of gun-flints exist at Muesnes in Berry, in Galicia, and at Avio in the Tyrol. (See MINERALOGY.)

FLOAT-BOARDS, in *mechanics;* boards fixed to the water-wheels of undershot mills, serving to receive the impulse of the stream.

FLOATING BREAKWATER. This marine contrivance may consist of a series of square frames of timber, connected by mooring-chains, or cables attached to anchors, or blocks of marble. The frame-work may be made of logs of yellow pine, from 30 to 50 feet long and from 18 to 20 inches square, bolted together very firmly, and increased in height as the situation may be boisterous, in order to break the violence of the agitated waves, and allow the vessels riding within these quadrangular basins more safety and protection. Such *breakwaters* are admirably adapted to bathing-places and swimming stations, since they

will always produce smooth water, and protect the machines.

Floating Bridge; a bridge made in the form of a redoubt, consisting of two boats covered with planks.

Floating Light; a hollow vessel of tinned iron plate, made in the form of a boat, with a reflector or lantern, for the purpose of saving those who may have the misfortune to fall overboard in the night.

Flood-Gate; a gate or sluice which may be opened or shut at pleasure for the admission or exclusion of the water.

Flood-Mark; the mark which the sea makes on the shore at the highest tide, otherwise called *high-water-mark*.

Floor Timbers are those parts of the ship's timbers which are placed immediately across the keel, and upon which the bottom of the ship is framed; to these the upper parts of the timbers are united, being only a continuation of floor timbers upwards.

Florentine Work; a kind of mosaic work, consisting of precious stones and pieces of marble. The Florentines were distinguished for this kind of work—hence the name.

Florin is sometimes used for a coin, and sometimes for a money of account. The florin coin is of different values. The gold florins are, most of them of a coarse alloy, some of them not exceeding thirteen or fourteen carats, and none of them seventeen and a half. As to silver florins, those of Holland are worth about 1*s.* 8*d.*

Flourish; an appellation sometimes given to the decorative notes which a singer or instrumental performer adds to a passage, with the double view of heightening the effect of the composition, and of displaying his own flexibilty of voice or finger. There is nothing of which a sensible performer will be more cautious than of the introduction of *flourishes*, because he is never so much in danger of mistaking, as when he attempts to improve his author's ideas. With performers of little taste, plain passages are indiscriminate invitations to ornament; and too frequently in the *flourish*, the beauty of a studied simplicity is at once overlooked and destroyed. Auditors who are fonder of execution than of expression, and more alive to flutter than to sentiment, applaud these sacrifices to vanity; but those who prefer nature to affectation, and listen in order to *feel*, know exactly how to value such performers.

Flower de Lis, or Flower de Luce, in *heraldry;* a bearing representing the lily, called the *queen of flowers*, and the *true hieroglyphic of royal majesty;* but of late it is become more common, being borne in some coats one, in others three, in others five, and in some *semée*, or spread all over the escutcheon in great numbers.

Flowers, in *chemistry;* a term formerly applied to a variety of substances procured by sublimation, in the form of slightly cohering powder: hence, in all old books, we find mention made of the flowers of antimony, arsenic, zinc, and bismuth, which are the sublimed oxides of these metals, either pure or combined with a small quantity of sulphur: we have also still in use, though not generally, the terms *flowers* of sulphur, benzoin, &c.

Flower Trade in Holland. Haarlem was formerly the centre of this trade. In 1636 and 1637, a real tulip mania prevailed in Holland. Bulbs, which the seller did not possess, were sold at enormous prices, on condition that they should be delivered to the purchaser at a given time. 13,000 florins were paid for a single Semper Augustus; for three of them together, 30,000 fl.; for 148 grains weight, 4500 fl.; for 296 grains of Admiral Liefkenshoek, more than 4000 fl.; for Admiral Enkhuizen, more than 5000, &c. For a Viceroy, on one occasion, was paid 4 tons of wheat, 8 tons of rye, 4 fat oxen, 8 pigs, 12 sheep, 2 hhds. of wine, 4 bbls. of beer, 2 bbls. of butter, 1000 lbs. of cheese, a bundle of clothes, and a silver pitcher. At an auction in Alcmaer, some bulbs were sold for more than 90,000 fl. An individual in Amsterdam gained more than 68,000 florins, by this trade, in four months. In one city of Holland, it is said, more than 10,000,000 tulip bulbs were sold. But when, on account of the purchasers refusing to pay the sums agreed upon, the States General (April 27, 1637) ordered that such sums should be exacted, like other debts, in the common way, the extravagant prices fell at once, and a Semper Augustus could be had for 50 florins: yet the profits of raising rare tulips were afterwards considerable; and, even at present, we find 25 to 150 fl. the price of a single rare tulip, in the catalogues of the Haarlem florists.

Until the time of the French revolution, the florists of Haarlem obtained their bulbs principally from Lisle, and other towns in Flanders, where the clergy were engaged in raising them. They afterwards carried on the business themselves; but the whole trade is now of little importance. Even after the decline of this trade, Alcmaer did not lose its reputation for possessing the first amateurs and connoisseurs in flowers. Persons in independent circumstances engaged in cultivating flowers, particularly hyacinths. Florists obtain their supplies, not only of hyacinths, but also of ranunculuses, auriculas, pinks, anemonies, &c., the demand for which has been gradually increasing, partly from that source, and partly from foreign countries. Haarlem still continues to be the emporium for the most beautiful of these articles.—Hyacinths first began to rise in estimation in 1730. In that year, 1850 fl. were paid for passe-non-plus-ultra, and in the same proportion for others. Between Alcmaer and Leyden there are more than 20 acres of land appropriated to hyacinths alone, which thrive best in a loose and sandy soil. There are still 12 or 13 great florists in and around Haarlem, besides a number of less importance. They send their flowers to Germany, Russia, England, &c., and even to Turkey and the Cape of Good Hope.

Flowing; the position of the sheets or lower corners of the principal sails, when they are loosened to the wind, so as to receive it more nearly perpendicular than when they are close-hauled, although more obliquely than when going before the wind. A ship is, therefore, said to have a flowing sheet, when the wind crosses the line of her course nearly at right angles; that is to say, a ship steering due north, with the wind at the east, or directly on her side, will have a flowing sheet; whereas, if the sheets were extended close aft, she would sail two points nearer the wind, viz., N. N. E.

Fluates, in *chemistry;* salts first discovered by Scheele, and distinguished by the following properties: When sulphuric acid is poured upon them, they emit acrid vapours of fluoric acid, which corrode glass. When heated, several of them phosphoresce. They are not decomposed by heat, nor altered by combustibles. They combine with silica by means

of heat. Most of them are sparingly soluble in water.

FLUENT, in *fluxions*; the flowing quantity, or that which is continually increasing or decreasing, whether line, surface, solid, &c.

FLUID; an appellation given to all bodies which yield, without separation, to the slightest pressure, easily move among themselves, and accommodate themselves to all changes of position, so as always to preserve a level surface. All fluids, except those in the form of air or gas, are incompressible in any considerable degree. All fluids gravitate or weigh in proportion to their quantity of matter, not only in the open air, or *in vacuo*, but in their own elements. Although this law seems so consonant to reason, it was supposed by ancient naturalists, who were ignorant of the equal and general pressure of all fluids, that the component parts, or the particles of the same element, did not gravitate or rest on each other; so that the weight of a vessel of water, balanced in air, would be entirely lost when the fluid was weighed in its own element.

The following experiment seems to leave this question perfectly decided: take a common bottle, corked close, with some shot in the inside to make it sink, and fasten it to the end of a scale beam; then immerse the bottle in water, and balance the weight in the opposite scale; afterwards open the neck of the bottle, and let it fill with water, which will cause it to sink; then weigh the bottle again. Now it will be found that the weight of the water which is contained in the bottle is equal to the difference of the weights in the scale, when it is balanced in air; which sufficiently shows that the weight of the water is the same in both situations. As the particles of fluids possess weight as a common property of bodies, it seems reasonable that they should possess the consequent power of gravitation which belongs to bodies in general. Therefore, supposing the particles which compose fluids to be equal, their gravitation must likewise be equal; so that in the descent of fluids, when the particles are stopped and supported, the gravitation being equal, one particle will not have more propensity than another to change its situation; and, after the impelling force has subsided, the particles will remain at absolute rest.

From the gravity of fluids arises their pressure, which is always proportioned to the gravity. For if the particles of fluids have equal magnitude and weight, the gravity or pressure must be proportional to the depth, and equal in every horizontal line of fluid; consequently, the pressure on the bottom of vessels is equal in every part. The pressure of fluids upwards is equal to the pressure downwards, at any given depth. For, suppose a column of water to consist of any given number of particles, acting upon each other in a perpendicular direction, the first particle acts upon the second with its own weight only; and, as the second is stationary, or fixed by the surrounding particles, according to the third law of motion, that action and reaction are equal, it is evident that the action or gravity, in the first, is repelled in an equal degree by the reaction of the second; and, in like manner, the second acts on the third, with its own gravity added to that of the first; but still the reaction increases in an equivalent degree, and so on throughout the whole depth of the fluid.

The particles of a fluid, at the same depth, press each other equally in all directions. This appears to rise out of the very nature of fluids; for, as the particles give way to every impressive force, if the pressure amongst themselves should be unequal, the fluid could never be at rest, which is contrary to experience; therefore we conclude that the particles press each other equally, which keeps them in their own places. This principle applies to the whole of a fluid as well as a part. This disposition on the part of all fluids to preserve a state of equilibrium between themselves may be illustrated by a very simple experiment.

If we take a deep glass vesssel, and having filled it with water, immerse in it another tube, closed at top, the tendency to a state of equilibrium will be apparent by the compression of the air in the tube; but if we withdraw the cork, the water will ascend, the upper pressure of the fluid being as great as that which tends to keep the water in the vessel.

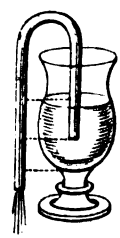
If four or five glass tubes, of different forms, be immersed in water, when the corks in the ends are taken out, the water will flow through the various windings of the different tubes, and rise in all of them to the same height as it stands in the straight tube; therefore the drops of fluids must be equally pressed, in all directions, during their ascent through the various angles of the tube; otherwise the fluid could not rise to the same height in them all. From the mutual pressure and equal action of the particles of fluids, the surface will be perfectly smooth, and parallel to the horizon. If, from any exterior cause, the surface of water has some parts higher than the rest, these will sink down by the natural force of their own gravitation, and diffuse themselves into an even surface. (See HYDROSTATICS.)

FLUIDITY; the state of bodies when their parts are very readily movable in all directions with respect to each other. Many useful and curious properties arise out of this modification of matter, which form the basis of the mechanical science called *hydrostatics*, and are of considerable importance in chemistry. But the attention of the chemist is chiefly directed to the state of fluidity as it may affect the component parts of bodies. A solid body may be converted into a fluid by heat. The less the temperature at which this is effected, the more fusible the body is said to be.

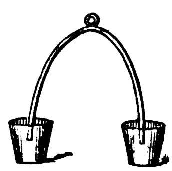
All fluids, not excepting the fixed metals, appear, from various facts, to be disposed to assume the elastic form, and this the more readily the higher the temperature. When a fluid is heated to such a degree that its elasticity is equal to the pressure of the air, its interior parts rise up with ebullition. The capacity of a dense fluid for caloric is greater than that of the same body when solid, but less than when in the elastic state. If this were not the case, the assumption of the fluid and elastic state would be scarcely at all progressive, but effected, in most cases, instantly as to sense. (See CALORIC.) The state of dense fluidity appears to be more favourable to chemical combination than either the solid or elastic state. In the solid state, the cohesive attraction prevents the parts from obeying their chemical tendencies; and, in the elastic state, the repulsion be-

tween the parts has, in a great measure, the same effects.

FLUIDS, MOTION OF. This subject will be fully discussed under HYDRAULICS and PIPES; we here notice only a few general principles. The motion of fluids, viz., their descent below or rise above the common surface or level of the source or fountain, is caused either, 1. by the natural gravity or pressure of the fluid contained in the reservoir or fountain; or, 2. by the pressure or weight of the air on the surface of the fluid in the reservoir, when it is, at the same time, either taken off or diminished, on some part, in aqueducts or pipes of conduit; 3. by the spring or elastic power of compressed or condensed air, as in the common water engine; 4. by the force of pistons, as in all kinds of forcing-pumps, &c.; 5. by the power of attraction, as in the case of tides. There is one apparent exception to the laws of fluids which must be noticed here. In a syphon fluids ascend as well as descend, and actually rise to a point higher than their natural level.



We have in this case a cup partly filled with water, and a bent tube is seen drawing off its fluid contents. To cause the water to flow over the top of the tube, the lips must be applied at the lower extremity, and having exhausted it of the air, the pressure of that without drives up the water, and the flow will continue as long as any remains in the vessel. Now the real cause of the ascent of the fluid in the first limb may be traced to the fact of the second tube being longer, and, as such, its fluid contents heavier. It descends by the ordinary laws of gravitation, and a new portion is continually forced up to supply its place.



A very beautiful application of this instrument to domestic purposes is shown in the diagram. Two little cups which may be firmly attached to the lower limbs of the syphon, at all times fit it for use by retaining the fluid in the tube. It is also of great importance for decanting acrid fluids, as acids, which might burn the lips of the operator.

FLUOR-SPAR. See MINERALOGY.

FLUORIC ACID is prepared by mixing pure fluor-spar, in coarse powder, with twice its weight of sulphuric acid, in a leaden or silver retort, and applying heat. The acid distils over in vapour, and must be collected in a receiver of the same metal surrounded by ice. At the temperature of 32° Fahrenheit, fluoric acid is a colourless fluid, and remains in that state at 59°, if preserved in well stopped bottles; but when exposed to the air, it flies off in dense white fumes, which consist of the acid in combination with the moisture of the atmosphere. Its specific gravity is 1.0609; but its density may be increased, by gradual additions of water, to 1.25. Its affinity for water is far greater than that of the strongest sulphuric acid. When a drop of it falls into water, a hissing noise is heard, similar to what is occasioned by plunging a red-hot iron into that liquid. Its odour is extremely penetrating, and its vapour dangerous to inspire. When applied to the skin, it instantly disorganizes it, and produces the most painful wounds. It acts energetically on glass; the transparency of the glass is instantly destroyed, caloric is evolved, and the acid boils, and, in a short time, disappears entirely, a colourless gas being the sole product.

This gas has received the name of *fluo-silicic acid*, because it is regarded as a compound of fluoric acid and silica. Another mode of procuring it in a visible state is to mix fluor-spar with pounded glass, and, introducing the mixture into a glass retort, to add sulphuric acid, and apply heat: the gas will make its appearance in abundance, and may be received in glass jars over the mercurial bath. It is about 48 times denser than hydrogen. When brought into contact with water, it is instantly absorbed, depositing its silica in a white, gelatinous mass, which is a hydrate of silica. It produces white fumes when suffered to pass into the atmosphere. From the strong affinity of fluoric acid for silica, it cannot be preserved in glass bottles; and is therefore kept in vessels of lead or silver. For the same reason, fluoric acid is employed for etching on glass—its only important application. The glass is covered with a thin coat of wax, or is brushed over with a solution of isinglass in water; and, when this is dried, lines are easily traced by a graver. It is then exposed to the action of the acid in the state of gas; the parts of the glass thus exposed are soon corroded, the impression being more or less deep, according to the time during which it is exposed. Such a method, were it possible to obviate completely the defect from the brittleness of glass, has, from the hardness of that substance, the important advantage over copper, that the impressions do not become less delicate from the fineness of the lines being diminished by the pressure in throwing them off. Different methods have been proposed to render the method practicable; and engravings, though not of much delicacy, have even been taken.

As all other acids are compound, Gay-Lussac and Thénard conceived the fluoric acid as such also, and adopted the opinion that it is composed of a certain combustible body and oxygen gas. They accordingly attempted to decompose it by means of some substance which has a strong affinity for oxygen, and employed potassium for that purpose. When that metal is brought into contact with fluoric acid, a violent action ensues, accompanied with an explosion, unless the experiment is cautiously conducted. Hydrogen gas is disengaged, and a white solid is produced, which has all the properties of fluate of potash; the explanation of which, given upon this view, was, that the hydrogen arises from the decomposition of water, that the oxygen of that fluid combines with the potassium, and that the potash so formed unites with the fluoric acid. They infer, therefore, from their experiments, that the strongest fluoric acid hitherto prepared contains water.

On the other hand, Sir H. Davy contended that fluoric acid, in its strongest form, is anhydrous; for, on combining it with ammoniacal gas, a dry fluate of ammonia is formed, from which no water can be expelled by heat. He maintained, also, that fluoric acid is composed, not of an inflammable base and oxygen, but of hydrogen united with a negative electric body, analogous to chlorine, to which he has given the name of *fluorine*. According to this view, when the metal potassium is brought into contact with fluoric acid, the hydrogen is not derived from water, but from the acid, and the supposed fluate of potash is a compound of fluorine and potassium.

The phenomena are explained with the same ease by either theory, although the arguments upon which they depend are thought, by the majority of chemists, to preponderate in favour of the view proposed by Sir Humphry Davy. Fluoric acid forms salts by uniting with several bases. Five fluates have hitherto been found native; viz., the fluate of lime, or fluor-spar, the fluo-silicate of alumine, or topaz, the fluate of cerium, the double fluate of cerium and yttria, and the double fluate of soda and alumine, or cryolite. The four latter are very rare minerals, but the first is abundant. Potash unites with fluoric acid in two proportions, forming a fluate and a bifluate, the former of which consists of one atom, and the latter of two atoms of acid united with one atom of the alkali.

A neutral fluate of soda may be obtained directly from fluoric acid and carbonate of soda. It melts with more difficulty than glass; 100 parts of water, at 212° Fahrenheit, dissolve only 4.3 of it. Neutral fluate of ammonia is more volatile than sal-ammoniac. It is easily obtained by heating one part of dry sal-ammoniac, with a little more than two parts of fluate of soda, in a crucible of platinum, with its lid turned upwards. The earthy fluates are best formed by digesting their recently precipitated moist carbonates in an excess of fluoric acid. That of barytes is slightly soluble in water, and readily in muriatic acid.

The neutral fluates of fixed bases are fusible at a high temperature, and are not decomposed by heat and combustible matter; nor does any acid, excepting the boracic, effect their decomposition, provided they are free from moisture. When digested, on the contrary, in concentrated sulphuric, phosphoric, or arsenic acids, the fluoric acid is disengaged, and may be recognised by its property of corroding glass. If, instead of glass, the fluor-spar be mixed with dry vitreous boracic acid, and distilled in a glass vessel with sulphuric acid. the proportions being 1 part boracic acid, 2 fluor-spar and 12 sulphuric acid, the gaseous substance formed is of a different kind, and is called *fluo-boric acid*. Its density to that of air is as 2.371 to 1.000. It is colourless. Its smell is pungent. It cannot be breathed without suffocation. It extinguishes combustion, and reddens vegetable blues. It has no action on glass, but a very powerful one on vegetable and animal matter, converting them into a carbonaceous substance. It has a singularly great affinity for water. When it is mixed with air, or any gas which contains watery vapour, a dense white cloud appears, which is a combination of water and fluo-boric acid gas. From this circumstance, it forms an exceedingly delicate test of the presence of moisture in gases. Fluo-boric acid gas is rapidly absorbed by water.

When potassium is headed in fluo-boric acid gas, it inflames, and a chocolate-coloured solid, wholly devoid of metallic lustre, is the sole product. On putting this substance into water, a part of it dissolves, and a solution of fluate of potash is obtained, the insoluble matter being boron. Accordingly, fluoboric acid gas is inferred to be a compound of fluoric and boracic acids. It unites with ammoniacal gas in three proportions, forming salts, one of which is solid, and the two others liquid. Other compounds of this acid, with salifiable bases, are scarcely known.

Flute; a portable instrument, blown with the breath, and consisting of a tube of box or ivory, furnished with holes at the side for the purpose of varying its sounds. Its name is derived from the word *fluta*, the Latin name of the lamprey, or small eel taken in the Sicilian seas, because, like that fish, it is long and perforated at the side. The flute was in great esteem with the ancient Greeks and Romans. (See Tibiæ.)

The *German flute* is, as its name implies, a wind instrument of German invention, consisting of a tube formed of several joints or pieces screwed into each other, with holes disposed along the side, like those of the common flute. It is stopped at the upper end, and furnished with movable brass or silver keys, which, by opening and closing certain holes, serve to temper the tones to the various flats and sharps. In playing this instrument, the performer applies his under lip to a hole about two inches and a half from the upper extremity, while the fingers, by their action on the holes and keys, accommodate the tones to the notes of the composition.

Flutes, in *architecture;* channels or furrows cut perpendicularly in the shafts of columns. Fluting the shafts of columns is a practice never omitted in any great and finished Grecian work. It therefore seems probable that it had some relation to the original type: perhaps the furrowed trunk might have suggested the idea. It is, however, a beautiful ornament, which is applied with equal happiness to break the otherwise heavy mass of a Doric shaft or to obviate an inconsistent plainness in the other orders.

Flux; a general term made use of to denote any substance or mixture added to assist the fusion of minerals. In the large way, limestone and fluor-spar are used as fluxes. The fluxes made use of in assays, or philosophical experiments, consist usually of alkalies, which render the earthy mixtures fusible by converting them into glass.

Alkaline fluxes are either the crude flux, the white flux, or the black flux. Crude flux is a mixture of nitre and tartar, which is put into the crucible with the mineral intended to be fused. The detonation of the nitre with the inflammable matter of the tartar is of service in some operations, though generally it is attended with inconvenience on account of the swelling of the materials, which may throw them out of the vessel. White flux is formed by introducing equal parts of a mixture of nitre and tartar, by moderate portions at a time, into an ignited crucible. In the detonation which ensues, the nitric acid is decomposed, and flies off with the tartaric acid; and the remainder consists of the potash, in a state of considerable purity. This has been called *fixed nitre*. Black flux differs from the preceding in the proportion of its ingredients. In this the weight of the tartar is double that of the nitre, on which account the combustion is incomplete, and a considerable portion of the tartaric acid is decomposed by the mere heat, and leaves a quantity of coal behind, on which the black colour depends. It is used where metallic ores are intended to be reduced, and effects the purpose by combining with the oxygen of the oxide.

Fluxion, in the *Newtonian Analysis*, denotes the velocity with which a flowing quantity increases by its generative motion, by which it stands contradistinguished from a fluent or flowing quantity, which is constantly and indefinitely increasing, after the manner that a surface is described by the motion of a line, or a solid by the motion of a surface.

Or, a fluxion may be otherwise defined as the

magnitude by which any flowing quantity would be uniformly increased in a given portion of time, with the generating celerity, at any proposed position or instant, supposing it thence to continue invariable.

Fluxional Analysis, or analysis of fluxions and flowing quantities, is distinguishable from the differential calculus by its notation.

The invention of the fluxional analysis does more honour to the powers of the human mind than perhaps any discovery of this or any preceding age; it opens to us a new world, and extends our knowledge, as it were, to infinity; it carries us beyond those bounds which seem prescribed to our mental powers, and leads to investigations and results which must otherwise have ever remained in impenetrable obscurity.

Within the narrow compass to which this article must necessarily be confined, the reader will not expect a minute detail of the principles of fluxions. It will be sufficient to observe that all finite magnitudes are here conceived to be resolved into infinitely small ones, supposed to be generated by motion, as a line by the motion of a point, a superficies by a line, and a solid by a superficies,—of which they are the elements, moments, or differences.

The art of finding these infinitely small quantities, or the velocities by which they are generated, and of working on them, and discovering other infinite quantities by their means, makes what is called the *direct method of fluxions*. And the method of finding the fluents or flowing quantities, these fluxions being given, is what constitutes the *inverse method*.

What renders the knowledge of infinitely small quantities of such great use and extent is that they have relations to each other, which the finite magnitudes whereof they are the infinitesimals have not.

Thus, for example, in a curve of any kind whatever, the infinitely small difference of the ordinate and absciss have the ratio to each other, not of the ordinate and absciss, but of the ordinate and subtangent; and, of consequence, the absciss and ordinate being known, will give the subtangent; or, which amounts to the same, the tangent itself.

The method of notation in fluxions, introduced by the inventor, Sir Isaac Newton, is as follows:—

The variable or flowing quantity, to be uniformly augmented, as suppose the absciss of a curve, he denotes by the final letters v, x, y, z; and their fluxions by the same letters with dots placed over them, thus, $\dot{v}, \dot{x}, \dot{y}, \dot{z}$. And the initial letters a, b, c, d, &c., are used to express invariable quantities.

Again, if the fluxions themselves are also variable quantities, and are continually increasing or decreasing, he considers the velocities with which they increase or decrease, as the fluxions of the former fluxions, or second fluxions, which are denoted by two dots over them, thus, $\ddot{y}\ \ddot{x}\ \ddot{z}$.

After the same manner one may consider the increase and diminution of these as their fluxions also, and thus proceed to the third, fourth, &c., fluxions, which will be denoted thus, $\dddot{y}\ \dddot{x}\ \dddot{z}$, $\ddddot{y}\ \ddddot{x}\ \ddddot{z}$, &c.

Lastly, if the flowing quantity be a surd, as $\sqrt{x-y}$, he denotes its fluxion by $(\sqrt{x-y})^{\cdot}$; if a fraction $\frac{xx}{d-y}$, it is denoted by $\left(\frac{xx}{d-y}\right)$.

Sometimes, however, the fluxions of compound quantities are expressed by placing the letter F, or f, before them; thus, instead of $(\sqrt{(x-y)}^{\cdot})$, is written F. $\sqrt{(x-y)}$, or $f.\ \sqrt{(x-y.)}$ At other times the fluxion is denoted by F, and the fluent by f; so that

$$\left.\begin{array}{ll} \text{F.} & \sqrt{(x-y)} \\ \text{F.} & \dfrac{x+ax^2}{b+x} \end{array}\right\} \text{denote the fluxions of} \left\{\begin{array}{l} \sqrt{(x-y)} \\ \dfrac{x+ax^2}{b+x} \end{array}\right.$$

$$\left.\begin{array}{ll} f. & \dot{x}\sqrt{(x+ax^2)} \\ f. & \dfrac{\dot{x}b}{x+ax^2} \end{array}\right\} \text{denote the fluents of} \left\{\begin{array}{l} \dot{x}\sqrt{(x+ax^2)} \\ \dfrac{b\dot{x}}{x+ax^2} \end{array}\right.$$

(See SURDS.)

FLY is a name given to a certain appendage to many machines, either as a regulator of their motions or as a collector of power. When used as a regulator, the fly is commonly a heavy disk or hoop, balanced on its axis of motion, and at right angles to it; though sometimes a regulating fly consists of vanes or wings, which, as they are whirled round, meet with considerable resistance from the air, and thus soon prevent any acceleration in the motion; but this kind of regulator should rarely, if ever, be introduced in a working machine, as it wastes much of the moving force. When the fly is used as a collector of power, it is frequently seen in the form of heavy knobs at the opposite ends of the straight bar, as in the coining press.

FOCILE MAJUS, in *anatomy;* the greater bone of the arm, called *ulna;* or greater bone of the leg, called *tibia*. The lesser bone of the arm or leg is called *focile minus*.

FOCUS, in *optics*, is a point wherein several rays concur or are collected, after having undergone either refraction, or reflection. This point is thus denominated, because, the rays being here brought together and united, their joint effect is sufficient to burn bodies exposed to their action; and hence this point is called the *focus*, or burning point. It must be observed, however, that the focus is not, strictly speaking, a point; for the rays are not accurately collected into one and the same place or point, owing to the different nature and refrangibility of the rays of light, to the imperfections in the figure of the lens, and other similar impediments. The focus, therefore, is a small circle, which Huygens has demonstrated to be one eight the thickness of the lens, when it is convex on both sides; that is, it cannot be less than this, but, in imperfect glasses, it exceeds the above measure sometimes considerably.

FŒTUS, in *anatomy;* a term applied to the offspring of the human subject, or of animals, during its residence in the womb,

FOG. There is a constant ascent of watery particles from the surface of the earth, occasioned by the evaportation from masses of water and moist bodies. Part of the water which rises in vapour is intimately united with the atmospheric air, which holds it in solution. This portion of aqueous matter is invisible, and exists in the greatest quantity in very warm and serene weather. Thus, in the hot days of summer, any cold body (as a vessel filled with iced water) is immediately covered with little globules of water, which are the vapour of the atmosphere precipitated. But when the air is saturated, the watery particles which continue to rise are no longer dissolved, but remain suspended in vesicular vapours, which form clouds when they rise to a great height, and fogs when they hover near the surface of the earth.

Fogs are more frequent in those seasons of the year when there is a considerable difference of temperature in the different parts of the day; as, for instance, in autumn, when, in the warmest part of the day, the air is capable of holding a great quantity of aqueous matter in solution, which, on cooling towards evening, it is no longer capable of dissolving. In hot weather, the air is not so easily saturated, and in cold weather, the process of evaporation is very slow, so that, in these cases, fogs are less common. In low, moist places, and in confined places, as valleys, forests, bays or lakes, surrounded by high lands, they are much more prevalent than in open countries, or elevated spots, where they are quickly dispersed by the winds. Fogs are very frequent in the arctic regions, where the sudden depression of temperature is enormously below the mean temperature. Fogs will be most frequent over shallow water, which sooner partakes of the temperature of the bottom than the deep water. The end of the deep water is known near the banks of Newfoundland, by the sudden commencement of the fogs. The thick fogs which appeared during Captain Franklin's expedition, prove that the sea is very shallow, and the mean temperature not very low, upon that part of the arctic coast.

There is another atmospherical phenomenon, which has been called *dry fogs*. In 1783, all Europe was enveloped with a dry fog, at the moment of a simultaneous volcanic action in Iceland and Calabria. In 1755, before the earthquake which destroyed Lisbon, a similar fog overspread the Tyrol and Switzerland. It appeared to be composed of earthy particles reduced to an extreme degree of fineness. A *fog-bank* is an appearance in hazy weather, which frequently resembles land at a distance, but which vanishes as you approach it.

Foil; a thin leaf of metal, placed under transparent substances, such as precious stones, for the sake of improving their colour, and heightening their lustre, the light, which passes through the transparent body, being reflected by the metal. Figuratively, any thing that serves to set off another object, by improving its external appearence.

Foil is also used to signify the sheet of amalgam laid on the back side of a mirror, which enables it to reflect a complete image.

Foil, in *fencing;* a blunt sword, or one tipped with a button or cork, covered with leather.

Foliage, in *architecture;* a kind of ornament in cornices, friezes, &c., representing the leaves of plants.

Fomahant, in *astronomy;* a fixed star, of the first magnitude, in the constellation Aquarius.

Fomentation, in *medicine*, is the external application of a fluid, as warm as the patient can bear it. Two flannel cloths are dipped in that liquor, one of which is wrung as dry as possible, and immediately applied to the part affected. This cloth lies on till the heat has evaporated, and the other is then applied. By this alternate application, the part affected is constantly supplied with warmth, for 15 minutes, or half an hour, as occasion may require.

Food, *comparative nutritive properties of*. An interesting report on this subject was presented to the French minister of the interior, by Messrs. Percy and Vauquelin, members of the Institute. In bread, every 100lbs. is found to contain 80lbs. of nutritious matter; butcher meat, averaging the different sorts, contains only 35lbs. in 100; French beans (in the grain), 92lbs. in 100; broad beans 89lbs.; peas, 93 lbs.; lentils (a species of half pea, little known in this country), 94lbs. in 100; greens and turnips, which are the most aqueous of all vegetables used in culinary purposes, furnish only 8 lbs. of solid nutritious substance in 100; carrots (from whence an inferior kind of sugar is produced), 14lbs.; and what is remarkable, as being opposed to the old theory, 100lbs. of potatoes yield only 25 lbs. of nutriment; 1 lb. of good bread is equal to 2½lbs. of potatoes; and 75lbs. of bread and 30lbs. of meat are equal to 300lbs. of potatoes; ½lb. of bread and 5oz. of meat are equal to 3lbs. of potatoes; 1 lb. of potatoes is equal to 4 lbs. of cabbage and 3lbs. of turnips; and 1lb. of rice bread or French beans is equal to 3 lbs. of potatoes.

Food, *abstinence from*. The more that animals enjoy the qualities of youth, strength, and activity, the greater is the increase and developement of their parts, and the greater the necessity for an abundant supply of food. Of many individuals exposed to an absolute abstinence of many days, the young are always the first to perish. Of this the history of war and shipwreck offers in all ages too many frightful examples. There are several instances on record, of entire abstinence from food for an extraordinary length of time. Captain Bligh, of the Bounty, sailed almost 4,000 miles in an open boat, with occasionally a single small bird not many ounces in weight, for the daily sustenance of seventeen people. In the opinion of Rhedit, animals support want much longer than is generally believed. A civet cat lived ten days without food, an antelope twenty, and a very large wild cat also twenty; an eagle survived twenty-three day, a badger one month, and several dogs thirty-six days. In the *Memoirs of the Academy of Sciences*, there is an account of a bitch, which having been accidently shut up alone in a country house, existed for forty days without any other nourishment than the stuff on the wool of a mattress, which she had torn to pieces. A crocodile will live two months without food, a scorpion three, a bear six, a chameleon eight, and a viper ten. Valliant had a spider that lived nearly a year without food, and was so far from being weakened by abstinence, that it immediately killed another large spider, equally vigorous but not so hungry, which was put in along with it. John Hunter inclosed a toad between two stone flower-pots and found it as lively as ever after fourteen months. Land-tortoises have lived without food for eighteen months; and Baker is known to have kept a beetle in a state of abstinence for three years. It afterwards made its escape. Dr. Shaw gives an account of two serpents which lived in a bottle without any food for five years.

Foot; a measure of length, derived from the length of the human foot, containing 12 linear inches.

Square foot, is a square whose side is one foot, and is therefore equal to 144 square inches.

Cubic foot, is a cube whose side is one foot, and the cube contains 1728 cubic inches.

Forage, in *military* affairs, denotes the provisions brought into the camp by the troops for the sustenance of the horses.

Foramen, in *anatomy;* a perforation or opening, as—*Foramen cæcum*, an opening at the basis of the cranium; and also in the middle of the tongue. *Foramen opticum*, the hole transmitting the optic nerve, &c.

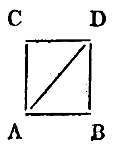
Force, in *mechanics*, denotes that unknown cause

which produces a change in the state of a body, as to motion, rest, pressure, &c.; that is, whatever produces or tends to produce motion, or a change of motion in any body, is called *force*. According to this definition, the muscular power of animals, as likewise pressure, impact, gravity, &c., are considered as forces, or sources of motion, it being evident, from daily experience, that bodies exposed to the free action of any of these are either put into motion, or have their state of motion changed. All forces, however various, are measured by the effects which they produce in like circumstances, whether the effect be creating, accelerating, retarding, or deflecting motions; the result of some general and commonly observed force is taken for unity, and with this any others may be compared, and their proportions represented by numbers or lines. Under this point of view they are considered by the mathematician; all else falls within the province of the universal philosopher, or the metaphysician.

When we say that a force is represented by a right line, A B, it is to be understood that it would cause a material point, situated at rest in A, to run over the line A B, which is called the direction of the force, so as to arrive at B at the end of a given time, while another force would cause the same point to have moved a greater or less distance from A in the same time. (*See the figure below.*) Mechanical forces may be reduced to two sorts; one of a body at rest, the other of a body in motion. The former is that which we conceive as residing in a body when it is supported by a plane, suspended by a rope, or balanced by the action of a spring, &c., being denominated *pressure, tension, force*, or *vis mortua, solicitatio, conatus movendi*, and which may always be estimated or measured by a weight, viz., the weight that sustains it. To this class of forces may also be referred centripetal and centrifugal forces, though they reside in a body in motion, because these forces are homogeneous to weights, pressures, or tensions of any kind.

The force of a body in motion is a power residing in that body so long as it continues its motion; by means of which it is able to remove obstacles lying in its way, to lessen, destroy, or overcome the force of any other moving body, which meets it in an opposite direction; or to surmount the largest dead pressure or resistence, as tension, gravity, friction, &c., for some time, but which will be lessened or destroyed by such resistance as lessens or destroys the motion of the body. This is called *vis motrix*, moving force, or motive force, and, by some late writers, *vis viva*, to distinguish it from the *vis mortua*, spoken of before.

Composition of Forces may be thus defined: If two or more forces, differently directed, act upon the same body, at the same time, as the body in question cannot obey them all, it will move in a direction somewhere between them. This is called the *composition* and *resolution* of forces or of motion, and may be illustrated in the following manner: Suppose a body, A, to be acted upon by a force in the direction A B, while, at the same time, it is impelled by another force in the direction A C, it will then move in the direction A D; and if the lines A B, A C, be made of lengths proportionate to the forces, and the lines C D,



D B, be drawn parallel to them, so as to complete the parallelogram A B D C, then the line which the body A will describe, will be the diagonal A D; and the length of this line will represent the force with which the body will move. But if the body be impelled by equal forces, acting at right angles to each other, it will move in the diagonal of a square. Instances in nature, of motion produced by several powers acting at the same time, are innumerable. A ship impelled by the wind and tide is one well known; a paper kite acted upon in one direction by the wind, and in another by the string, is another instance.

Animal Force, as applied to Machinery. All machines are impelled either by the exertion of animal force or by the application of the powers of nature. The latter comprise the potent elements of water, air, and fire. The former is more common, yet so variable as hardly to admit of calculation. It depends not only on the vigour of the individual, but on the different strength of the particular muscles employed. Every animal exertion is attended by fatigue; it soon relaxes, and would speedily produce exhaustion. The most profitable mode of applying the labour of animals, is to vary their muscular action, and revive its tone by short and frequent intervals of repose.

The ordinary method of computing the effects of human labour is, from the weight which it is capable of elevating to a certain height in a given time, the product of these three numbers expressing the absolute quantity of performance. This was reckoned by Daniel Bernoulli and Desagulier at 2,000,000 lbs. avoirdupois, which a man could raise one foot in a day. But our civil engineers have gone much farther, and are accustomed, in their calculations, to assume, that a labourer will lift 10 lbs. to the height of ten feet every second, and is able to continue such exertion for ten hours each day, thus accumulating the performance of 3,600,000. But this estimate seems to be drawn from the produce of momentary exertions, under the most favourable circumstances; and it therefore greatly exceeds the actual results, as commonly depressed by fatigue, and curtailed by the unavoidable waste of force.
